# CONTENTS

## *JANUARY*

EDITORIAL: Partial liquid ventilation – turning back a PAGE on evolution ........ 1
*K. P. Kelly*

### CLINICAL INVESTIGATIONS

Absence of memory for intraoperative information during surgery under adequate general anaesthesia .......... 3
*I. F. Russell and M. Wang*

Extradural morphine gives better pain relief than patient-controlled i.v. morphine after hysterectomy ........... 10
*M. Eriksson-Mjoberg, J.-O. Svensson, O. Almkvist, A. Olund and L. L. Gustafsson*

Target-controlled infusion of alfentanil for postoperative analgesia: a feasibility study and pharmacodynamic evaluation in the early postoperative period ........ .. 17
*M. C. O. Van den Nieuwenhuyzen, F. H. M. Engbers, A. G. L. Burm, A. A. Vletter, J. W. van Kleef and J. G. Bovill*

I.v perioperative ketoprofen in small children during adenoidectomy .... 24
*E. Nikanne, H. Kokki and K. Tuovinen*

Effect of clonidine on gastric emptying of liquids....... 28
*T. Asai, C. McBeth, J. I. M. Stewart, J. Williams, R. S. Vaughan and I. Power*

Effect of temperature during cardiopulmonary bypass on gastric mucosal perfusion .... 34
*N. D. Croughwell, M. F. Newman, E. Lowry, R. D. Davis jr, K. P. Landolfo, W. D. White, J. L. Kirchner and M. G. Mythen*

Non-invasive measurement of cerebral blood volume in volunteers .... 39
*A. K. Gupta, D. K. Menon, M. Czosnyka, P. Smielewski, P. J. Kirkpatrick and J. G. Jones*

Use of modified fluid gelatin and hydroxyethyl starch for colloidal volume replacement in major orthopaedic surgery .... 44
*R. Beyer, U. Harmening, O. Rittmeyer, S. Zielmann, F. Mielck, S. Kazmaier and D. Kettler*

Cardiorespiratory changes during gynaecological laparoscopy by abdominal wall elevation: comparison with carbon dioxide pneumoperitoneum ................. 51
*A. Casati, G. Valentini, S. Ferrari, R. Senatore, A. Zangrillo and G. Torri*

### LABORATORY INVESTIGATIONS

Isoflurane increases the uptake of glutamate in synaptosomes from rat cerebral cortex ...... 55
*M. Larsen, E. Hegstad, J. Berg-Johnsen and I. A. Langmoen*

Sevoflurane modulates both $\text{GABA}_A$ and $\text{GABA}_B$ receptors in area CA1 of rat hippocampus ........... 60
*K. Hirota and S. H. Roth*

Volatile anaesthetic effects on calcium conductance of planar lipid bilayers formed with synthetic lipids or extracted lipids from sarcoplasmic reticulum ...... 66
*T. Andoh, T. J. J. Blanck, I. Nikonorov and E. Recio-Pinto*

Effects of magnesium sulphate on atrioventricular conduction times and surface electrocardiogram in dogs anaesthetized with sevoflurane .... 75
*S. Akazawa, R. Shimizu, Y. Nakaigawa, R. Ishii, S. Ikeno and R. Yamato*

P25780 1

### SHORT COMMUNICATIONS

Prolonged peribulbar anaesthesia with indwelling catheter: a preliminary report of 217 cases .... 81
*J.-M. Bernard and J.-L. Hommeril*

Continuous brachial plexus infusion of butophanol–mepivacaine mixtures for analgesia after upper extremity surgery ........... 83
*Z. Wajima, T. Shitara, Y. Nakajima, C. Kim, N. Kobayashi, H. Kadotani, H. Adachi, G. Ishikawa, K. Kaneko, T. Inoue and R. Ogawa*

Validation of pulse oximetry for monitoring of hypoxaemic episodes in the late postoperative period .............. 86
*K. Stausholm, S. Rosenberg-Adamsen, L. Edvardsen, H. Kehlet and J. Rosenberg*

Spinal anaesthesia inhibits central temporal summation. 88
*M. Curatolo, S. Petersen-Felix, L. Arendt-Nielsen and A. M. Zbinden*

Neuromuscular effects of rocuronium in patients receiving beta-adrenoreceptor blocking, calcium entry blocking and anticonvulsant drugs .................... 90
*P. B. Loan, F. M. Connolly, R. K. Mirakhur, N. Kumar and P. Farling*

Low-dose rocuronium improves conditions for tracheal intubation after induction of anaesthesia with propofol and alfentanil .... 92
*K. Barclay, K. Eggers and T. Asai*

Effects of desflurane and isoflurane on splanchnic microcirculation during major surgery ...... 95
*J. O'Riordan, H. A. O'Beirne, Y. Young and M. C. Bellamy*

Effect of low-dose dopamine on serum concentrations of prolactin in critically ill patients .... 97
*A. R. Bailey and K. R. Burchett*

Coupling of spontaneous ventilation to heart beat during benzodiazepine sedation .... 100
*D. C. Galletly and P. D. Larsen*

### CASE REPORTS

Anaesthetic management of a patient with an automatic implantable cardioverter defibrillator *in situ* ......... 102
*P. C. A. Kam*

Ether in an isoflurane vaporizer and the use of vapour analysers in safe anaesthesia .... 107
*A. N. Strachan and M. N. Richmond*

### CORRESPONDENCE

Cardiac arrest after Caesarean section under subarachnoid block .... 109

Haemoglobin changes during anaesthesia .... 111

Unexpected difficulty in the lighted stylet-aided tracheal intubation via the laryngeal mask .... 111

### BOOK REVIEWS

*Postoperative Management of the Cardiac Surgical Patient* 113

*Key Questions in Anaesthesia*, 2nd Edn .... 113

*Pain Treatment Centres at a Cross-roads: a Pratical and Conceptual Reappraisal* .... 113

## *FEBRUARY*

EDITORIALS: I. Extradural analgesia: does it affect progress and outcome in labour? .. 115
*E. M. McGrady*

II. Recent advances in prophylaxis against deep vein thrombosis .... 118
*T. Wheatley and P. S. Veitch*

III. Thermoregulation in critical illness .. 121
*I. T. Campbell*

### CLINICAL INVESTIGATIONS

Metabolic effects of i v propacetamol, metamizol or external cooling in critically ill febrile sedated patients ......... 123
*B. Poblete, J.-A. Romand, C. Pichard, P. Konig and P. M. Suter*

Hormonal responses and cardiac filling pressures in head-up or head-down position and pneumoperitoneum in patients undergoing operative laparoscopy 128
*E. A. Hirvonen, L. S. Nuutinen and O. Vuolteenaho*
Effects of clonidine on the pituitary hormonal response to pelvic surgery 134
*F. M. Lyons, S. Bew, P. Sheeran and G. M. Hall*
Modelling the volume of expandable body fluid spaces during i.v. fluid therapy 138
*L. Ståhle, A. Nilsson and R. G. Hahn*
Volume kinetics of Ringer's solution in female voluteers 144
*R. G. Hahn, D. Drobin and L. Ståhle*
The lumbar extradural structure changes with increasing age 149
*T. Igarashi, Y. Hirabayashi, R. Shimizu, K. Saitoh, H. Fukuda and H. Mitsuhata*
Do anxiety or hypocapnia predispose to apnoea after induction of anaesthesia? 153
*G. B. Drummond and N. M. M. El-Farhan*
Comparison of induction and recovery between sevoflurane and halothane supplementation of anaesthesia in children undergoing outpatient dental extractions 157
*S. A. Ariffin, J. A. Whyte, A. F. Malins and G. M. Cooper*
Plasma bupivacaine concentrations associated with continous extradural infusions in babies 160
*J. M. Peutrell, K. Holder and M. Gregory*
Analgesia after day-case knee arthroscopy: double-blind study of intra-articular tenoxicam, intra-articular bupivacaine and placebo 163
*T. M. Cook, J. P. Tuckey and J. P. Nolan*
Brain tissue oxygenation in patients with cerebral occlusive disease and arteriovenous malformations 169
*W. E. Hoffman, F. T. Charbel, G. Edelman and J. I. Ausman*
Blood loss during trimester termination of pregnancy: comparison of two anaesthetic techniques 172
*J. E. Hall, W. S. Ng and S. Smith*
Use of heparinase modified thrombelastography in liver transplantation 175
*S. A. Harding, S. V. Mallett, T. D. Peachey and D. J. Cox*
Relationship between calculated blood concentration of propofol and electrophysiological variables during emergence from anaesthesia: comparison of bispectral index, spectral edge frequency, median frequency and auditory evoked potential index 180
*M. Doi, R. J. Gajraj, H. Mantzaridis and G. N. C. Kenny*

LABORATORY INVESTIGATIONS

Do local anaesthetics interact with dihydropyridine binding sites on neuronal L-type $Ca^{2+}$ channels? 185
*K. Hirota, T. Browne, B. L. Appadu and D. G. Lambert*
Effect of halothane on conventional protein kinase C translocation and down-regulation in rat cerebrocortical synaptosomes 189
*H. C. Hemmings jr and A. I. B. Adamo*
*In vitro* neuromuscular effects of valproic acid 197
*A. Nguyen and I. Ramzan*

REVIEW ARTICLE

Cytokines in anaeasthesia 201
*P. Sheeran and G. M. Hall*

SHORT COMMUNICATIONS

The laryngeal mask airway and the tracheal route for drug administration 220
*R. Alexander, H. Swales, A. Pickford and G. B. Smith*
Low-dose mivacurim supplementation of prilocaine i.v. regional anaesthesia 222
*J. M. Torrance, B. M. F. Lewer and D. C. Galletly*

CASE REPORT

Anaphylaxis associated with, but not caused by, extradural bupivacaine 224
*S. M. Rae, M. K. Milne and J. A. W. Wildsmith*

CORRESPONDENCE

Flow cytometry 227
ASA classification and perioperative variables as predictors of postoperative outcome 228
ASA classification and perioperative variables: graded anaesthesia score? 228
Effect of Sprotte needle orientation on spinal anaesthesia 229
Cardiac arrest after Caesarean section 230
Dose–response curve for anesthetics based on the Monod–Wyman–Changeux model 230
Failed intubation drill 231

BOOK REVIEWS

*Pharmacology in the Practice of Anaesthesia.* 232
*Reflex Sympathetic Dystrophy: A Re-appraisal* 232

**Errata** 233

## *MARCH*

EDITORIALS: I. Extracorporeal membrane oxygenation, a favourable outcome? 235
*G. J. Peek and R. K. Firmin*
II: Are there new solutions to old problems with weaning? 238
*J. M. Schneerson*

CLINICAL INVESTIGATIONS

Extracorporeal membrane oxygenation for transport of hypoxaemic patients with severe ARDs 241
*R. Rossaint, D. Pappert, H. Gerlach, K. Lewandowski, D. Keh and K. Falke*
Propofol anaesthesia and postoperative nausea and vomiting: quantitative systematic review of randomized controlled studies 247
*M. Tramèr, A. Moore and H. McQuay*
Meta-analytic conparison of prophylactic antiemetic efficacy for postoperative nausea and vomiting: propofol anaesthesia vs omitting nitrous oxide vs total i.v. anaesthesia with propofol 256
*M. Tramèr, A. Moore and H. McQuay*
A model of the electrocortical effects of general anaesthesia 260
*J. W. Sleigh and D. C. Galletly*
Role of vasopressin in the haemodynamic response to laparoscopic cholecystectomy 264
*A. D. Walder and A. R. Aitkenhead*
Pharmacodynamics and pharmacokinetics of rocuronium in intensive care patients 267
*H. J. Sparr, J. M. K. H. Wierda, J. H. Proost, C. Keller and K. S. Khuenl-Brady*
Predominant involvement of motor fibres in patients with critical illness polyneuropathy 274
*E. Hund, H. Genzwurker, H. Bohrer, H. Jakob, R. Thiele and W. Hacke*
Propofol attenuates formation of lipid peroxides in tourniquet-induced ischaemia-reperfusion injury 279
*S. Kahraman, K. Kilinç, D. dal and K. Erdem*
Auditory evoked response, median frequency and 95% spectral edge during anaesthesia with desflurane and nitrous oxide 282
*R. M. Sharpe, D. Nathwani, S. K. Pal, M. D. Brunner, C. Thornton, C. J. Doré and D. E. F. Newton*
Effect of percutaneous local anaesthetics on pain reduction during pulse dye laser treatment of portwine stains 286
*D. F. McCafferty, A. D. Woolfson, J. Handley and G. Allen*

## LABORATORY INVESTIGATIONS

Anaesthetic potency of inhalation agents is independent of membrane microviscosity ........ 290
*R. I. Norman, R. Hirst, B. L. Appadu, M. Mckay, P. Bradley, R. Griffiths and D. J. Rowbotham*

Effect of propofol on isolated human omental arteries and veins ........ 296
*S. M. Wallerstedt and M. Bodelsson*

Differential effects of clonidine and dexmedetomidine on gastric emptying and gastrointestinal transit in the rat.. 301
*T. Asai, W. W. Mapleson and I. Power*

## SHORT COMMUNICATIONS

Detection of inspiratory resistive loads after anaesthesia for minor surgery ........ 308
*G. B. Drummond and J. P. Cullen*

Does intrathecal fentanyl produce acute cross-tolerance to i.v. morphine? ........ 311
*D. W. Cooper, S. L. Lindsay, D. M. Ryall, M. S. Kokri, S. S. Eldabe and G. A. Lear*

Mechanism of femoral nerve palsy complicating percutaneous ilioinguinal field block ........ 314
*D. J. Rossario, S. Jacob, J. Luntley, P. P. Skinner and A. T. Raftery*

Effects of the pregnant uterus on the extradural venous plexus in the supine and lateral positions, as determined by magnetic resonance imaging ........ 317
*Y. Hirabayashi, R. Shimizu, H. Fukuda, K. Saitoh and T. Igarashi*

Effect of lipid and propofol on oxidation of haemoglobin by reactive oxygen species ........ 320
*N. Stratford and P. Murphy*

Validation of thoracic electrical bioimpedance as a porcine research tool ........ 323
*C. J. Broomhead, S. J. Wright, K. M. Kiff and P. S. Withington*

Effects on haemodynamics and catecholamine release of xenon anaesthesia compared with total i.v. anaesthesia in the pig ........ 326
*T. Marx, G. Froeba, D. Wagner, S. Baeder, A. Goertz and M. Georgieff*

Pregnenolone sulphate and pregnenolone do not interact with 5β-pregnanolone- and hexobarbitone-induced anaesthesia in the rat ........ 328
*M. D. Wang, G. Wahlström and T. Bäckström*

Antagonism of suxamethonium-induced jaw muscle contracture in rats ........ 332
*Y. Shi, R. J. Storella, M. M. Keykhah and H. Rosenberg*

## CASE REPORTS

Lumbovertebral syndrome after repeat extradural blood patch ........ 334
*J. H. McG. Palmer, D. W. Wilson and C. M. Brown*

## CORRESPONDENCE

Removal of LMA in children ........ 337
Predicting difficulty—clinical indices and their statistical equivalents ........ 338
Effect of amino acid infusion on body temperature during anaethesia ........ 338
Anatomical configuration of the spinal column as dertermined by magnetic resonance imaging ........ 339
Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume ........ 339
Management of rhabdomyolysis ........ 340
Rocuronium and vecuronium ........ 342
Intraoperative heat administration ........ 343
Extraction of nitric oxide and nitrogen dioxide using molecular sieve 5A ........ 343

## BOOK REVIEWS

*Interventional Pain Management* ........ 345
*Psychology of Pain* ........ 345

## *APRIL*

EDITORIALS: I: Recovery after major surgery: does the anaesthetic make any difference? ........ 347
*G. M. Chumbley and G. M. Hall*

II Low-dose dopamine: will there ever be a scientific rationale? ........ 350
*C. McCrory and A. J. Cunningham*

## CLINICAL INVESTIGATIONS

Effect of an upper respiratory tract infection on upper airway reactivity ........ 352
*N. Nandwani, J. H. Raphael and J. A. Langton*

Inhalation induction with sevoflurane: a double-blind comparison with propofol ........ 356
*A. Thwaites, S. Edmends and I. Smith*

Rapid inhalation induction in children: 8% sevoflurane compared with 5% halothane ........ 362
*P. E. Sigston, A. M. C. Jenkins, E. A. Jackson, M. R. J. Sury, A. M. Mackersie and D. J. Hatch*

Halothane–propofol anaesthesia for tracheal intubation in young children ........ 366
*D. Hansen, W. Schaffartzik, D. Dopjans, E. Heitz and H. W. Striebel*

Minimum alveolar concentration of desflurane for tracheal extubation in deeply anaesthetized, unpremedicated children ........ 370
*K. A. W. Cranfield and L. M. Bromley*

Increase in serum creatine phosphokinase concentrations after suxamethonium during sevoflurane or isoflurane anaesthesia in children ........ 372
*A. Kudoh, T. Sakai, H. Ishihara and A. Matsuki*

Hypnotic effect of i.v. propofol is enhanced by i.m. administration of either lignocaine or bupivacaine ........ 375
*I. Ben-Shlomo, M. Tverskoy, G. Fleyshman and G. Chernavsky*

Occupational exposure to desflurane and isoflurane during cardiopulmonary bypass: is the gas outlet of the membrane oxygenator an operating theatre pollution hazard? ........ 378
*K. Hoerauf, M. Harth, K. Wild and J. Hobbhahn*

Effects of chronic β-blockade on compensatory mechanisms during acute isovolaemic haemodilution in patients with coronary artery disease ........ 381
*D. R. Spahn, B. Seifert, T. Pasch and E. R. Schmid*

Perioperative myocardial cell injury: the role of troponins ........ 386
*H. Metzler, M. Gries, P. Rehak, Th. Lang, S. Fruhwald and W. Toller*

A study of the anatomy of the caudal space using magnetic resonance imaging ........ 391
*I. M. Crighton, B. P. Barry and G. J. Hobbs*

I.m. midazolam as premedication produces a concentration-dependent decrease in core temperature in male volunteers ........ 396
*T. Matsukawa, K. Hanagata, M. Ozaki, H. Iwashita, M. Koshimizu and T. Kumazawa*

Effect of clonidine and dexmedetomidine premedication on perioperative oxygen consumption and haemodynamic state ........ 400
*M. T. Taittonen, O. A. Kirvelä, R. Aantaa and J. H. Kanto*

Regional cerebral blood flow (SPECT) during anaesthesia with isoflurane and nitrous oxide in humans ........ 407
*P. Reinstrup, E. Ryding, L. Algotsson, L. Berntman and T. Uski*

Self-learning fuzzy logic control of neuromuscular block 412
*J. J. Ross, D. G. Mason, D. A. Linkens and N. D. Edwards*

## REVIEW ARTICLE

Congenital heart disease in adults ... 416
*D. Findlow and E. Doyle*

## SHORT COMMUNICATIONS

Wound infiltration with local anaesthetic after abdominal hysterectomy ... 431
*T. F. Cobby and M. F. Reid*
Induction characteristics of 2% propofol in children ... 433
*A. Borgeat, T. Fuchs and E. Tassonyi*
A study of mixing conditions during nitric oxide administration using simultaneous fast response chemiluminescence and capnography ... 436
*L. Foubert, K. Mareels, M. Fredholm, S. Lundin and O. Stenqvist*
Effects of acute administration of morphine on right atrial catecholamine content and heart rate in chronically morphine-treated rats ... 439
*J. V. Rabadan, M. V. Milanés and M. L. Laorden*

## CASE REPORTS

Obstructive sleep apnoea syndrome: is this an overlooked cause of desaturation in the immediate postoperative period? ... 442
*K. Vidhani and B. T. Langham*
Intentional asystole during endoluminal thoracic aortic surgery without cardiopulmonary bypass ... 444
*A. B. Baker, M. J. Bookallil and G. Lloyd*

## EQUIPMENT

A new method for measurement of anaesthetic partial pressure in blood ... 449
*M. A. Smith, S. M. Sapsed-Byrne and G. G. Lockwoood*

## ABSTRACTS

Proceedings of the Anaesthetic Research Society, Northwick Park Meeting, November 21–22, 1996 ... 453P

## CORRESPONDENCE

Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting ... 476
Ethanol monitoring during hysteroscopy ... 476
ACE inhibitors and renal protection ... 477
Possible mechanism to explain increased coagulability of blood after haemodilution ... 478
Regional anaesthesia in moyamoya disease ... 478
Converting pH and H$^+$: "a rule of thumb" ... 479
Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation ... 479
Anticholinesterases and subsequent duration of block of suxamethonium ... 480
I.v. anaesthetics and binding to calcium channels ... 481

## BOOK REVIEWS

*Pain Relief and Anesthesia in Obstetrics* ... 483

# Partial liquid ventilation—turning back a PAGE on evolution

On an evolutionary time scale, liquid ventilation is not new. Land-dwelling vertebrates derived from fish 350 million years ago, and fish continue to breathe through a liquid medium. However, the ability to sustain mammalian respiration artificially by a liquid ventilation technique is generally accredited to work in the early 1960s, where mice were kept alive breathing hyperbaric salt solutions.[1] The hyperbaric conditions were required in order that sufficient oxygen could be dissolved in solution to sustain cell respiration.

This was taken further by Clark and Gollan in 1966 when they described the use of silicone oils and fluorocarbons at atmospheric pressure in supporting the life of mice and cats receiving a liquid ventilation technique.[2] Silicone oils were found to be too toxic to use in living creatures but the perfluorocarbons showed more promising characteristics. Perfluorocarbons (PFC) are a group of stable, inert, colourless and odourless liquids which are not soluble in either lipids or water. Oxygen, carbon dioxide and most other gases, however, are dissolved. The solubility of oxygen in PFC is of the order of 50 ml per 100 ml of solvent, and carbon dioxide 200 ml per 100 ml of solvent at atmospheric pressure (i.e. 20 and three times the solubility of each gas in plasma, respectively). They have a low predisposition to react with biological tissue. PFC may be derived from organic compounds (e.g. benzene) by replacement of carbon bound hydrogen atoms with fluorine, by heating the organic compound with cobalt trifluoride or by electrochemical fluorination techniques.[3]

Throughout the 1970s and 1980s, further work was done in animals, both with normal lungs[4] and in models of prematurity and lung injury.[5 6] Two milestones have been reached in the past 10 yr. First, until recently liquid ventilation required relatively complex extracorporeal equipment to oxygenate and remove carbon dioxide from the liquid medium. This involved filling the functional residual capacity with PFC and using tidal volumes consisting entirely of liquid, and was known as (total) liquid ventilation. Fuhrman, Paczan and DeFrancisis[7] described how it was possible to sustain ventilation in pigs with a hybrid technique, that is a medium of perfluorocarbon but using a standard ventilator (so called perfluorocarbon associated gas exchange (PAGE) and also known as partial liquid ventilation (PLV)), while Greenspan and colleagues described the first human use of this respiratory medium (in preterm infants with respiratory distress syndrome).[8 9]

Within the past year there has been the publication of the first human experience of this technique in acute respiratory distress syndrome in adults.[10 11] The 10 adult patients cited were already being supported by extracorporeal gas exchange. These studies were uncontrolled, but appeared to show that instillation of the PFC Perflubron ($C_8F_{17}Br$) was "safe in these patients with severe respiratory failure receiving extracorporeal life support and may be associated with improvement of gas exchange and pulmonary compliance".

In addition to their characteristics quoted above, the mode of action of PFC is speculative at present. PFC are dense although not appreciably more viscous than water. They therefore accumulate in the most dependent parts of the lung. This density implies that inflammatory debris "floats" on top of the PFC and, as it were, is lavaged out of the alveoli. Furthermore, PFC have a low surface tension (for example Perflubron has a surface tension 18 dyn $cm^{-1}$).[11]

It has been speculated that Perflubron opened up previously collapsed segments in the most dependent parts of the lung making them available for gas exchange, that is expanding functional residual capacity. The surface tension reducing properties may help to keep the re-opened alveoli expanded, essentially a surfactant-like function. It was also argued that the density of the PFC displaced some blood to the non-dependent (better ventilated) portions of lung, optimizing ventilation/perfusion matching.[11]

Further, the lavage of inflammatory mediators could have played a role by acting as continuing "fuel" for substances causing capillary leak in addition to washing out proteins which inhibit surfactant function.

What is unclear is how much gas exchange actually occurs through PFC themselves, as opposed to gas exchange through aerated lung tissue.[12] Hirschl and colleagues did not mention if they pre-oxygenated the PFC before administration. Animal work using PFC equilibrated with 100% oxygen noted only slight deterioration in oxygenation immediately after administration, and the conclusion drawn from this was that the PFC itself contained a "reservoir" of oxygen which continued to supply oxygen during the transition period from gas to liquid ventilation.[7] One could postulate however, that there might be a more marked transient decrease in oxygenation if non-equilibrated PFC were used.

The only problems resulting from Perflubron, according to Hirschl and colleagues, seemed to be mucus plugging, which was relieved by more vigorous suction. Pneumothorax occurred in five patients during PLV, but only in one who did not already have a chest drain for pre-existing pneumothoraces.

More general concerns with regard to the use of PFC include slow elimination from the body. A study in beagles showed traces of the PFC Caroxin-F in the lung (but also liver, kidney, spleen, heart, brain skeletal muscle and fat) 3 yr after 1-h exposure to liquid ventilation. Elimination of this PFC is primarily by evaporation and removal via the lymphatics. Not surprisingly therefore, the highest concentrations were noted in the lungs and associated lymph nodes. There was also an increase in serum alkaline phosphatase and cholesterol concentrations with an elevated peripheral white cell count, which returned to normal within a week. Follow-up platelet counts at 6 and 9 months were reduced significantly, although still within the normal range.[13]

Despite these findings, there were no histological structural changes in the lung, liver, spleen, kidney, heart or brain attributable to PFC. There is, however, understandable anxiety in using an agent which is retained in the body for so long, even if it apparently does no harm.

On an important practical note, the radiodensity of the PFC makes interpretation of chest radiographs difficult for several weeks after administration. It is also believed that deep sedation may be required.[12] There is also the possibility (which is true of mechanical ventilation in general) that there may be impairment to venous return,[12] although Hirschl and colleagues found no change in cardiac index.

Current knowledge suggests a clinical potential. It may be a means of providing some of the benefits of surfactant therapy (as yet still experimental in acute lung injury, compared with its established place in the treatment of immature, surfactant deficient lungs), in addition to applying a graded degree of PEEP where it is needed most in ARDS (in collapsed, dependent lung areas). By reducing inappropriate overdistention of the lung, this could limit iatrogenic lung damage.

Whether these theoretical benefits can be translated into reality depends on further research. Without further investigation into this form of therapy, we may be missing the opportunity of a useful novel adjuvant therapy to support the injured lung, to add to other novel treatments such as inhalation of nitric oxide and extracorporeal lung support.

CLINICAL INVESTIGATIONS

# Absence of memory for intraoperative information during surgery under adequate general anaesthesia

I. F. Russell and M. Wang

## Summary

Using the isolated forearm technique (IFT), we wished to determine if patients known to be unresponsive to commands during general anaesthesia with nitrous oxide, halothane and neuromuscular blocking agents had any evidence of explicit or implicit recall. Two groups of women, studied in a single-blind sequential block design, heard different tapes, either a command and information tape ($n$=34) or radio static ($n$=34), throughout surgery. Four women (two radio static, two command) had unequivocal evidence of explicit recall for a period near the beginning or end of the procedure, at a time when the IFT was not being used. With or without hypnosis, category generation, serial position of category exemplars and word association tests did not reveal evidence of priming. We conclude that during light general anaesthesia with nitrous oxide, halothane and atracurium, patients had neither explicit nor implicit memory for information presented during a period when they are known to be unresponsive to commands. (*Br. J. Anaesth.* 1997; **78**: 3–9)

**Key words**
Anaesthesia, depth. Anaesthesia, general. Memory.

Over the past few years a belief has developed that postoperative tests of implicit memory (i.e. no explicit recall of a learning episode but test performance is altered) reveal that patients can process and recall auditory information presented to them during general anaesthesia. This subject has been discussed in depth at three international symposia entitled "Memory and Awareness under Anaesthesia".[1–3] Although results are mixed, virtually all of the evidence suggesting patients can process information during general anaesthesia has been obtained in patients undergoing surgery where neuromuscular blocking agents were used as an integral part of the anaesthetic technique.[4 5]

The use of the isolated forearm technique (IFT) has revealed that with some general anaesthetic techniques more than 70% of patients may be capable of responding to commands during surgery with no postoperative conscious (explicit) memory for these intraoperative events.[6–8] Clinical monitoring of arterial pressure, heart rate, sweating and tear production was of little benefit in predicting the conscious state of patients during surgery and no clinically useful relationship could be found between changes in these clinical variables and a patient's responses.[9] Further evidence that clinical signs cannot be used to determine reliably the occurrence of intraoperative awareness comes from another study where anaesthetic records were examined in detail after surgery: three experienced anaesthetists were unable to identify the anaesthetic records of patients known to have been aware during surgery from the records of matched controls who had not been aware.[10]

A major flaw in the methodology of studies investigating implicit memory in relation to general anaesthesia lies in the assessment of "adequate" anaesthesia. These studies used no direct means of establishing the conscious level of patients during anaesthesia, relying instead on clinical monitoring, an indirect, unreliable and imprecise method of assessing conscious levels in the presence of neuromuscular blocking agents.[11] Thus it is possible that in these previous studies clinical monitoring suggested adequate anaesthesia but all patients may not have been unconscious. If patients are awake during surgery, even with no explicit recall, then it is perhaps not surprising that sophisticated psychological tests reveal evidence of implicit memory.

While using the IFT we wished to investigate the occurrence of postoperative implicit recall when information was presented to patients during surgery at a time when they were non-responsive to commands.

## Patients and methods

Approval for the study was obtained form the Hull and East Yorkshire Ethics and Clinical Trials Committee. Informed consent was obtained from women (ASA I or II) with no hearing difficulty presenting for major gynaecological surgery. The possible use of hypnosis on day 3 was mentioned, but patients were advised that the use of hypnosis was

Wang, Department of Psychology, University of Hull, Cottingham Road, Kingston upon Hull, East Riding of Yorkshire, HU6 7RX. Accepted for publication September 5, 1996.

Correspondence to I F R.

optional and that separate consent would be obtained at that time.

After premedication with temazepam 20 mg orally, 1–2 h before operation, and after baseline readings had been obtained from the monitoring system, anaesthesia was induced with thiopentone 5 mg $kg^{-1}$. As soon as consciousness was lost (absence of response to command) 66% nitrous oxide in oxygen with halothane (0.5% set on the vaporizer) was commenced by manual mask ventilation. After tracheal intubation, facilitated by suxamethonium 1.5 mg $kg^{-1}$, mechanical ventilation of the lungs was continued with this same gas mixture via an Oxford Penlon mark II ventilator in its non-rebreathing configuration. End-tidal carbon dioxide concentration was maintained at 4–5%. When the action of suxamethonium began to wear off, atracurium 0.2–0.4 mg $kg^{-1}$ was used for more prolonged neuromuscular block.

The study included extensive automatic monitoring (with recording to computer hard disk) of haemodynamic, EEG and other psychophysiological variables, details of which are available from the authors. These data are not reported here as intraoperative cognitive status was determined directly using the IFT, as described in table 1. "Rescue" anaesthesia was built into the study design such that if the isolated forearm revealed persistent reflex movements or semi-purposive movements or a response to commands, the patient would receive thiopentone 1.5 mg $kg^{-1}$.

The IFT commands were incorporated into a prerecorded stimulus tape and the patients formed two groups, studied in a single-blind, sequential block design. Within 2 min of skin incision one of two continuous loop cassette tapes was played to the patient through open headphones. One group heard radio static throughout surgery (group RSG), while in the other group (group CG) a 1-min continuous loop cassette tape containing two commands was played. This latter tape contained two discrete 15-s messages (separated by 15 s). Each message was preceded by the patient's preferred name (twice) and the words "this is Dr Russell speaking": the first message was "if you can hear me I would like you to open and close the fingers of your right hand, open and close the fingers of your right hand"; the second message was "here are some special words I would like you to remember—"sour gooseberry, sharp lemon, green pear".

*Table 1* Summary of the isolated forearm technique

1. A padded arterial pressure cuff is placed around the right forearm
2. ECG electrodes, connected to a Relaxograph, are placed over the ulnar nerve just above the elbow joint and over the median nerve in the cubital fossa. Recording electrodes placed over the wrist and hypothenar eminence.
3. Anaesthesia is induced and a supramaximal stimulus obtained.
4. An appropriate dose of suxamethonium is administered for tracheal intubation and the patient is connected to the ventilator.
5. The response from the Relaxograph is checked.
6. As suxamethonium wears off the tourniquet is inflated and an appropriate dose of atracurium is administered.
7. Start the tape recorder.
8. Assess neuromuscular integrity at regular intervals.
9. Deflate the tourniquet at 20 min.
10. If further neuromuscular block is required re-inflate the tourniquet and administer a small dose of atracurium.
11. Repeat steps 8, 9, 10 as necessary

*Table 2* An example of the simple questions asked early in the interview, and the later cue questions used to elicit evidence of explicit memory

Simple questions
1. What was the last thing you remember before going to sleep?
2. What was the next thing you remember?
3. Can you remember anything in between?

Cue questions
I said I would play a tape recorder to you during surgery:
1 Do you know what was played to you on the tape?
2. Do you remember hearing anything?
3. Do you remember hearing anyone talking to you?
4. Do you remember anyone asking you to do anything?
5. Do you remember anyone asking you to do anything with a hand or arm?
6. Do you remember anyone asking you to do anything with your right hand or arm?

The tape was switched off before halothane was discontinued during skin closure. Residual neuromuscular block was antagonized , if required, with 0.5–1 ml of a glycopyrronium and neostigmine mixture (ratio 0.5 mg/2.5 mg in 1 ml). After extubation, papaveretum 0.5 ml i.m. and 0.5 ml i.v. was administered and the patient taken to the recovery room.

One to two hours later patients had a structured interview to elicit any conscious memories of the surgical period, of the tape played to them or evidence of dreaming. Cue questions which did not presuppose a particular answer were used to elicit evidence of factual recall (table 2). Patients were then asked to name five vegetables and after their answers were asked to name five fruits. A word association test was then performed with the following words, "father", "hill", "sour", "sharp", "green". Thus the study included three different types of probe for the same intraoperatively primed words: free (explicit) recall, word category and word association (implicit recall).

On the third day, patients were seen again and asked if they would consent to a second interview under hypnosis. If consent was not obtained for hypnosis then the original interview was repeated. If consent for hypnosis was obtained, patients walked to a side room and sat in a padded armchair with their forearms and hands resting on the arm rests. After a standard hypnotic induction the trance was deepened using a visualization technique and arm levitation. When hypnosis was thought to be adequate (i.e. arm levitation occurred) the patient was regressed to the preoperative period to the time when she was lying in bed awaiting transfer to the operating theatre. She was then asked to describe her feelings and the various events she experienced from that time to the present.

Because of the vivid "real life" experiences possible under hypnosis (Bennett, personal communication) it was felt essential to ensure that contact was maintained with the patient at all times to reduce the chance of some untoward occurrence. Thus just before the patient's experience of anaesthesia was investigated under hypnosis the following reassurance was given: "very soon you will be going off to sleep with your anaesthetic and I would like you to tell me what it feels like as you go off to sleep and what you are aware of as you go off to sleep. This time you will be able to speak to me and to hear me and you will be able to breathe normally; things you may not have been able to do during your anaesthetic". The original recovery interview was then repeated under hypnosis. Before wakening from hypnosis the women were advised that they would remember only as much of the hypnotic interview as they wished. General reassurance about recovery from surgery, mobility and ego strengthening were the final aspects of the hypnotic session.

If arm levitation was not obtained the interview continued (as described above), but the results were analysed as belonging to the appropriate non-hypnosis group.

Results were analysed using *t* tests,· chi-square tests and signal detection tests,[12] as appropriate.

## Results

We included 68 woman who were studied sequentially in the following single-blind manner: 17 command tape, 17 radio static, 17 radio static, 17 command tape. Some patients could not be interviewed adequately in recovery and others were not seen on day 3, hence the variation in numbers within the subgroups. Of those seen on the third day, seven women in group CG and 13 in group RSG refused hypnosis. This difference was not significant (chi-square test $P$=0.096).

*Table 3* Type of surgery, patient age, weight, time from induction to skin incision and duration of exposure to tape (mean (SD or range)). AH = Abdominal hysterectomy, VH = vaginal hysterectomy, other = other major gynaecological surgery. *Chi-squared test; †*t* test.

| Good dreams | 0 | 0 | 2 | 0 |

The time from induction of anaesthesia until skin incision, duration of tape exposure and other patient data are presented in table 3. There were no differences between the groups.

No patient responded to commands during surgery but two patients in group RSG and eight in group CG exhibited reflex responses to surgical stimulation (Fisher's exact test $P$=0.032). Both patients in group RSG exhibited reflex responses at skin incision and one had reflex movements later during uterine traction. Seven patients in group CG exhibited reflex movements at skin incision and two had reflex movements during uterine traction. The remaining patient in group CG responded reflexly during uterine traction.

Initially, with superficial questioning, no evidence of explicit recall for intraoperative events was obtained during any of the interviews. However, with specific prompting cue questions (table 2), five women provided evidence of explicit recall (table 4).

Tables 5–7 summarize the data with respect to investigation of implicit memory. Analysis of simple word counts (chi-square test), analysis of scores based on the serial position of target words in the list (*t* test) and application of signal detection tests[12] did not provide evidence of priming for target fruits in group CG. In a previous investigation of women presenting for gynaecological surgery in the same hospital, Charlton[5] established the normative frequency of occurrence of common fruits in response to a request "name the first five fruits that come to

*Table 5* Number of patients who included the "target" fruit in their list of five fruits in recovery Patients responding with both "pear" and "lemon" are also included in individual counts of "pear" and "lemon"

mind". The responses of groups RSG and CG, both in recovery and on day 3, were not different from each other or from this previously obtained norm (table 7).

No patient at any time, with or without hypnosis, replied with an appropriate response in the word pair test.

Overall these tests for implicit memory of intraoperative information indicated no differences between groups RSG and CG and thus no evidence of a priming effect as a result of the command tape. There was no evidence that hypnosis, as performed in this study, enhanced recall of the primed words.

## Discussion

It is generally accepted that explicit recall for intraoperative events or information is evidence of inadequate anaesthesia. Thus, by this criterion, five women were inadequately anaesthetized at some stage of the procedure. None of the five patients was aware of pain and only one was aware of surgery. All episodes of recall occurred during a period when the IFT was not in use (see appendix for individual patient details).

As the tape recorder was not switched on until shortly after skin incision, there is little doubt that the two women in group RSG (table 4, superscripts "a" and "b") who described voices suddenly being blocked out by a buzzing noise were awake during the early part of surgery. Neither of these women was aware of surgery and it is not known for how long they remained awake after skin incision. Interestingly, after the day 3 interview, patient "a" volunteered that she had been awake during a previous Caesarean section: this had not been mentioned during the preoperative discussions.

Three patients in group CG (table 4, superscripts "c", "d", "e") also produced evidence of being awake momentarily during surgery. Patient "c" recalled hearing voices, but not what was being said, and was aware of skin incision: this was not painful and she drifted off to sleep. On discontinuing halothane, patient "d" awoke more quickly than expected, just as the surgeon was inserting a vaginal pack at the end of vaginal hysterectomy: she recalls someone "doing something down there". Patient "e" exhibited six reflex responses over a 15-min period with no other clinical signs of light anaesthesia, but unfortunately a few minutes after receiving her single incremental dose of atracurium the IFT cuff burst and deflated, with paralysis of the arm until the end of surgery. On the third day as she emerged from her hypnotic state she was observed to be opening and closing the fingers of her right hand. When asked why she was doing this she said she had wanted to "straighten and relax her fingers like this" while under hypnosis but had been unable to do so.

There seems little doubt that "c" was awake during the early part of the procedure and "d" at the very end, but before accepting the experience of patient "e" at face value, the responses of the three women in group RSG should be noted (table 4, f, g, h) who, under hypnosis, claimed to have had recall. The first of these was sure that the first author (I. F. R.) had asked her to do something with her hand; the second believed the first author (I. F. R.) spoke to her reassuringly during surgery. If these are real memories then they occurred either very early or very late in the procedure, before or after the radio static tape, at a time when anaesthesia may have been incomplete. The third patient in group RSG claimed to have been aware of surgery and when asked to describe her experience she clearly described a laparoscopy: whether this was related to her own previous diagnostic laparoscopy or to a recent television programme on laparoscopic surgery which she had watched is unknown. Nevertheless, despite the possibility of fabrication, the experience described by patient "e" as she emerged from hypnosis corresponds so precisely to actual intraoperative events that it seems extremely likely that she did indeed have recall for a period when anaesthesia was less than adequate.

It is of interest that none of the five women with evidence of recall voiced this during the interview in recovery. On the contrary, of the four patients capable of answering the questions, recall was specifically denied in recovery. This finding adds further to the confusion surrounding the issue of the most appropriate time to interview patients in the postoperative period. If subjects are interviewed in the immediate postoperative period then the residual effects of general anaesthetic drugs undoubtedly has some effect on cortical function. On the other hand, delaying a test too long may lead to degradation of the specific memory trace and thus reduce the likelihood of linking intraoperative information with postoperative recall. On balance, Bennett[13] believes that the evidence does not favour testing memory "as soon after surgery as possible". To add further to the difficulties, the optimum time for testing recall may vary depending on which memory function is being tested, "from a few minutes to a few days".[4]

Despite previous results to the contrary[14 15] there was no evidence that hypnosis, as used in this study, improved recall of primed words. Possible reasons for lack of enhanced hypnotic recall in this study could be: (1) information was presented during adequate anaesthesia; (2) the hypnotic trance was not sufficiently deep; (3) the hypnotic interview technique was not appropriate (previous studies used ideomotor and non-verbal signalling as evidence of intraoperative memory[13–15]; (4) the reassurances given to the patients just before their hypnotic experience of anaesthesia may have implanted a suggestion that they would not be aware under anaesthesia and this implanted suggestion suppressed recall.

If adequate anaesthesia prevents encoding of auditorally presented material into long-term memory stores, then no amount of sophisticated psychological testing may extract the non-existent information.

In this study arm levitation was used as part of the technique for deepening the hypnotic state. There may be wide variations in susceptibility to hypnosis between subjects but, in general, those who attain arm levitation show substantially more hypnotic responsiveness than those who do not attain such levitation.[16] While lack of arm levitation does not necessarily imply that an individual subject is resistant to hypnosis, on average, such subjects obtain scores in the lower third of the Stanford hypnotic susceptibility scale (i.e. may be less responsive to hypnosis).[16] It seems unlikely that lack of an adequate depth of hypnotic trance was a cause for the absence of recall.

There is a suggestion that intraoperative instructions to perform a non-verbal response (e.g. touch your ear when you hear my voice again) may be a better indicator of recall for intraoperative information than verbal responses. Although the finger flexing response of the patient in whom the IFT cuff burst could be taken as evidence to support this view she was the only patient in the study to produce such a response and this followed exposure to a period when anaesthesia was known to be very light. Specifically designed studies of non-verbal responses have produced mixed results. Several of the investigations purporting to provide evidence for recall of suggestions for a non-verbal response had significant methodological or statistical inadequacies, or both, which makes interpretation of the results impossible.[4] There appears to be little conclusive evidence that suggestions for non-verbal behaviour during a postoperative interview are any more reliable than verbal responses as an indicator of recall for intraoperative information presented during general anaesthesia.

The reassurance given to the patients before their hypnotic experience of anaesthesia was felt to be important. Bennett suggests that intraoperative reminiscences can be powerful stimuli and should be approached with caution.[13] There would be little point in proceeding through the patient's anaesthetic experience under hypnosis only to find either that she "could not speak" (because of paralysis and intubation), "could not hear you" (because she was unconscious) and worst of all, stopped breathing (because of paralysis). While possible, it is unlikely that recall was impaired by the reassurances given during hypnosis before exploring intra-anaesthetic memory. Four of the five women with recall expressed their recall under hypnosis. Another woman, under hypnosis, was "gagging" on the tracheal tube and "pushing" against the ventilator as she emerged from "anaesthesia" and as the "tracheal tube was removed" she said, "God I feel crap". This was exactly the sequence of events and words used at the end of her real anaesthetic.

As in other studies,[13] this investigation provided clear evidence of confusion and fabrication when using hypnosis, thus emphasizing the importance of being able to verify the material claimed as recall. There were also other unforeseen problems which arose during hypnosis and it is as well that other investigators should be aware of these. The hypnotic sessions of nine women deviated from normal. These women all "broke down" and began crying at some stage during hypnosis. With the patient's permission the cause of the crying was investigated before continuing with the normal hypnotic interview. The most common reasons for crying were of a psychosexual nature: the woman's "wholeness" and "attractiveness" for future sexual relationships (five women); sexual abuse as a teenager by her father (one); and psychological/physical/sexual abuse by her husband (one). The two other causes of crying were an overwhelming fear of cancer (one) and fear of experiencing severe postoperative pain, as experienced after previous abdominal surgery (one).

The importance of direct assessment of a patient's conscious level during anaesthesia is emphasized by the lack of spontaneous movement from the three women with unequivocal evidence of recall for the time around the start of surgery: despite having a non-paralysed forearm none responded to skin incision. The unreliability of clinical monitoring is illustrated by the fact that only one of these three patients was suspected of being inadequately anaesthetized and this was confirmed by clear responses to command (see appendix).

Both premedication and neuromuscular blocking agents reduce the MAC value of inhalation anaesthetics and, taking these effects into account, it was estimated that the MAC value of the anaesthetic given was approximately 1.5 MAC. To assure surgical anaesthesia, a MAC value of 1.25–1.3 is recommended[17] but Cormack[18] stated that "With neuromuscular block, surgery can be carried out at less than 1 MAC, and this has proved satisfactory in millions of patients". In the absence of an end-tidal halothane concentration monitor in this study, it is impossible to estimate alveolar halothane concentration at the beginning of surgery but the anaesthetic was sufficient to prevent the perception of pain in all patients and only one woman (patient c) was aware of surgery (a painless skin incision). The times from induction to skin incision in the three women with recall for the start of surgery were 14 min (patient a), 12 min (patient b) and 5 min (patient c). These three epidoses emphasize the need for a higher concentration of volatile agent for the first few minutes of anaesthesia, particularly if no direct assessment of conscious levels is being made. Normal clinical signs do not ensure unconsciousness.

As with all negative results, the power of a study is important. Previous studies with a positive result using a similar methodology reported target words more often in the test group than in the control group: 2.4 *vs* 1.84,[19], 2.7 *vs* 0.9,[20] 1.5 *vs* 0.5.[21] A composite average response from analysis of these results suggests that our study had a power of 95% of detecting similar differences at the 0.05% level. While it is always possible that a type II error may have occurred, the responses of the two groups in this study were so similar that this seems unlikely.

In summary, there is no evidence from this investigation that women anaesthetized with nitrous oxide and halothane and who were unresponsive to commands at the time specific information was presented to them had either explicit or implicit memory for this information. Our results suggest that if intraoperative implicit learning occurred then it probably did so during episodes of inadequate anaesthesia. Further research in this area, if purporting to reflect an adequately anaesthetized state as opposed to some type of quasi-amnesia with paralysis, must include systematic, accurate and direct intraoperative monitoring of levels of consciousness with the IFT during the period when information is presented.

## Appendix

### DESCRIPTION OF EVENTS FOR PATIENTS WITH POSTOPERATIVE RECALL

*Table 4, patient "a": group RSG—no hypnosis*

This 95-kg patient was aware of someone opening her eyelid and I. F. R.'s voice asking her to do something. She found I. F. R.'s voice soothing and comforting. There was no pain, she was unaware of any other sensations and was not aware of skin incision. She then described the sudden onset of a buzzing noise which blocked everything out before she drifted off to sleep.

During the 10 min after intubation, while she was being prepared for abdominal hysterectomy, her pupils remained moderately dilated, she continued to produce tears, and heart rate and arterial pressure remained high. Despite her being assigned to the white sound group, the first author (I. F. R.) asked her directly to "squeeze my fingers". When she responded, which she did twice (at 6 min and 10 min) she was reassured everything was going well and she would soon be asleep. Thiopentone 100 mg was given on each occasion. At skin incision (14 min) she moved her hand reflexly but there was no response to direct command. No other commands were given. The white sound tape was switched on at 16 min. It is of some relevance that she had "a bad experience" during her second Caesarean section and after this she woke up crying and was "upset" for several days. The Caesarean section anaesthetic record was obtained subsequently from another hospital: this revealed the use of minimal doses of drugs, quite inadequate for a 100-kg patient (thiopentone 250 mg and 50% nitrous oxide only before delivery; 63% nitrous oxide, fentanyl 100 µg and 0.2% trilene after delivery). It seems likely that she had been awake during that Caesarean section but had no conscious recall of the events Unfortunately, she did not give consent for hypnosis so further investigation of her Caesarean section experience was not possible. Details of this "bad experience" did not emerge during the preoperative interview!

During her postoperative interviews she responded with "pear" in recovery and on day 3, in third and fourth positions, respectively.

*Table 4, patient "b": group RSG—hypnosis*

This patient was aware of female voices asking someone to "pass something" when the sudden onset of a buzzing noise prevented her from hearing anything else before she went to sleep. There was no pain. It is more than likely that this patient heard the surgical team during preparations for vaginal hysterectomy and then the white noise masked everything. She was unaware of surgery. There were no responses of any type from the isolated arm.

During the postoperative interviews she did not reply with any target fruits, either in recovery or on day 3.

*Table 4, patient "c": group CG—hypnosis*

This patient, undergoing abdominal hysterectomy, claims to have heard talking, to have been aware of people "at the bottom" and was aware of skin incision. There was no pain and she drifted off to sleep before she could become anxious. There were no responses of any type from the isolated arm.

During postoperative interviews she gave no target fruits in recovery but in the word association test responded to "sour" with "lemon". On day 3 she gave "pear" in fifth position and responded to "sour" with "grapefruit".

*Table 4, patient "d": group CG—hypnosis*

This patient undergoing vaginal hysterectomy was aware of someone "doing things to her down there, things she did not like". Because of this she felt she was a "dirty person".

This patient had a very poor body image and regarded anything to do with genitalia as "dirty". After the tape was switched off and halothane was discontinued she woke up very quickly as the surgeon was placing a vaginal pack.

In recovery she gave "lemon" in first position. On day 3 she gave lemon in third position.

*Table 4, patient "e": group CG—hypnosis*

During hypnosis this patient claimed to have been aware of talking. She does not know when, or what was said. She felt the colour "green" had particular significance. On emerging from hypnosis she was opening and closing the fingers of her right hand. When asked why she was doing this she said that she wanted to "straighten and relax her fingers" while hypnotized but had been unable to do so. She was sure she had been asked to do something with her fingers.

Under anaesthesia for abdominal hysterectomy there were six reflex responses of the isolated forearm over the first 15 min of surgery. There was no other clinical evidence of light anaesthesia and no response to command. At 16 min the cuff was inflated and atracurium 20 mg administered. The arm remained unparalysed and there were no further movements. However, 10 min after this second dose of atracurium the IFT cuff burst and the right arm became paralysed, remaining so until the end of surgery. The command tape continued playing during this time. At the end of surgery while her trachea was being extubated the surgeon made several loud comments regarding the "green swabs" used by anaesthetists in this hospital.

In recovery she was too sedated to respond adequately and only a single response was obtained. This was in the word pair test: she promptly gave "swab" to the cue word "green". On day 3 under hypnosis she responded with "lemon" in first position and pear in fourth position. In the word association test she emphasized the importance of green but did not know why this colour should have such a special significance. In the word association test she responded to "green" with both "emerald" and "tree".

# Extradural morphine gives better pain relief than patient-controlled i.v. morphine after hysterectomy

M. ERIKSSON-MJÖBERG, J.-O. SVENSSON, O. ALMKVIST, A. ÖLUND AND L. L. GUSTAFSSON

## Summary

We examined if patient-controlled analgesia (PCA) with i.v. morphine provided comparable postoperative analgesia after hysterectomy as extradural morphine, without increasing the incidence of side effects. The study ($n$=40) was randomized and double-blind. An extradural catheter was inserted before surgery and anaesthesia was standardized. The extradural group received extradural morphine 0.06 mg kg$^{-1}$ by the end of surgery and a second dose 6 h later. The i.v. group received an i.v. infusion of morphine 0.2 mg kg$^{-1}$ after surgery. PCA with morphine 0.04 mg kg$^{-1}$ i.v. was used in both groups. Pain relief (VAS), side effects and cognitive functions were evaluated for 18 h. Plasma samples were obtained for analysis of morphine concentrations. Mean consumption of PCA morphine was 2.4 mg h$^{-1}$ for the i.v. group and 1 mg h$^{-1}$ for the extradural group. Despite unlimited access to morphine, the i.v. group had higher VAS scores as the extradural group ($P$<0.001). Plasma concentrations of morphine varied 8–10-fold in both groups. In the i.v. group itching, tiredness, blurred vision and vertigo correlated with cumulative consumption of i.v. morphine whereas in the extradural group this correlation existed only for tiredness. Both groups showed reduced ability to perform tests of cognitive function; indicating a central effect of both i.v. and extradural morphine, despite markedly lower plasma morphine concentrations in the extradural group. (*Br. J. Anaesth.* 1997; **78**: 10–16)

**Key words**
Analgesia, postoperative. Analgesics opioid, morphine. Analgesia, patient-controlled. Anaesthetic techniques, extradural.

A single dose of extradural morphine provides better and longer lasting pain relief after major surgery than a single dose of i.v. or i.m. morphine.[1–3] However, the clinical use of extradural morphine is hampered by side effects such as pruritus, vomiting, delayed gastric emptying and, most importantly, respiratory depression.[4] Respiratory depression usually occurs within 12 h, although it may occur later, up to 24 h after administration of extradural morphine.[1 2 4] This delay necessitates supervision of patients for 12–24 h[4]. I.v. morphine can also produce respiratory depression.[5]

It is well known that the need for i.v. opioids in the postoperative period varies between patients undergoing similar types of surgery even though the same anaesthetic techniques are used.[6] In the postoperative period, patient-controlled analgesia (PCA) is a valuable method for providing pain relief.[5–7] The PCA device allows patients to administer i.v. opioids according to individual needs. Consequently, after major surgery it may be possible to evaluate if the consumption of i.v. morphine gives equivalent or superior pain relief compared with single doses of extradural morphine. This has been examined in some controlled studies with contradictory results.[7–10]

Loper and Ready found that patients given repeated doses of extradural morphine after arthrotomy reported significantly lower pain scores than those using PCA with i.v. morphine.[10] In contrast, Weller and co-workers[7] could not find any significant differences in pain ratings between patients receiving single doses of morphine by the extradural route and those who received i.v. morphine using PCA after orthopaedic surgery. A third study reported that after Caesarean section, extradural morphine gave superior pain relief than PCA with i.v. morphine.[8] In that study, the PCA doses were 1–2 mg and the lockout time was 6 min.[8] The low doses may have reduced the full potential of the PCA technique.

Plasma concentrations of morphine and their relation to reported side effects are seldom investigated after i.v. and extradural administration in the postoperative period. We have found no study comparing the efficacy of repeated doses of extradural morphine with higher doses (2–4 mg) of i.v. morphine administered by PCA. In this study, we have compared the effects of PCA administration of i.v. morphine with extradural morphine during the initial 18 h after hysterectomy. The first hypothesis was: patient-controlled administration of i.v. morphine with an initial bolus dose of i.v. morphine can

give as good or better pain relief as single doses of extradural morphine combined with PCA administration of i.v. morphine. The second hypothesis was: PCA i.v. morphine administration does not result in more side effects than extradural morphine.

## Patients and methods

The study was approved by the Huddinge Hospital Ethics Committee. The study was double-blind and patients were allocated randomly to one of two groups: i.v. or extradural (table 1).

### PATIENT RECRUITMENT

We examine 84 consecutive patients undergoing elective hysterectomy (table 2). Exclusion criteria included backache, obesity, psychiatric disease and age more than 60 yr. Five patients who had agreed to join the study were not included because of administrative problems such as lack of beds in the post-operative unit. We calculated body mass index (BMI, weight (kg) divided by height$^2$ (m)) and considered $<25$ kg m$^{-2}$ to be normal.[11] Patients with a BMI value less than 32 kg m$^{-2}$ were accepted. We studied 40 female patients who fulfilled the inclusion and exclusion criteria.

All patients met the anaesthetist (M. E.-M.) the day before surgery and were given full verbal and written information on the study. They were instructed on how to use the visual analogue scale (VAS) for pain rating and the PCA device was demonstrated. We also performed baseline cognitive tests (see neuropsychological assessments), blood-gas analysis of arterial blood, and venous blood samples were obtained as a zero reference for plasma concentrations of morphine.

### ANAESTHESIA AND SURGICAL PROCEDURES

The anaesthetic procedure was standardized. Patients were given diazepam 10 mg orally in the ward, 1 h before the start of anaesthesia. All patients had an extradural catheter inserted at lumbar segments L3–L4 or L2–L3. Mepivacaine 20 mg ml$^{-1}$ with adrenaline was given extradurally as two consecutive doses. After a test dose of 3 ml, another 12 ml were given to women younger than 50 yr and 9 ml to women older than 50 yr. When the anaesthetic level for pinprick reached T10–12, patients were anaesthetized with thiopentone 5 mg/kg body weight and fentanyl 0.2 mg. After pancuronium 1 mg, intubation was facilitated with suxamethonium 1 mg/kg body weight. Isoflurane 0.5% was given in a mixture of nitrous oxide and oxygen to maintain anaesthesia. A single dose of pancuronium 3 mg was given before the start of surgery and additional 1-mg doses when needed. A top-up dose of mepivacaine 8 ml with adrenaline 10 mg ml$^{-1}$ was given during surgery, 1 h after the first dose.

*Table 2* Patient recruitment

| | | |
|---|---|---|
| Considered for enrolment | 84 patients | |
| Refused extradural anaesthesia | 10 | |
| Administrative problems | 5 | |
| Excluded | 29 | |
| History of: | | |
| Back pain | | 15 |
| Psychiatric disease | | 2 |
| Easily induced vomiting after opioid administration | | 2 |
| High body mass index | | 5 |
| Poor fluency in Swedish | | 5 |
| Included in study | 40 | |

Administration of isoflurane was discontinued when the skin was closed, and neuromuscular block was antagonized with neostigmine 2.5 mg.

All patients underwent abdominal hysterectomy with or without salpingo-oophorectomy via a Pfannenstiel incision (39 patients). A midline incision was used in one patient only.

### STUDY DESIGN

Blinded solutions of extradural and i.v. morphine, and saline were prepared by the hospital pharmacy and stored in glass bottles. At closure of the peritoneum, patients in the extradural group received a single dose of extradural morphine 0.4 mg ml$^{-1}$, corresponding to 0.06 mg/kg body weight (table 1). The mean dose given was 4 (SD 0.5) mg. Patients in the i.v. group received the same volume of 0.9% saline.

After surgery patients were awakened and the trachea extubated. After a mean time of 15 min after the end of surgery, patients were brought to the recovery room where they were monitored for a minimum of 18 h. On arrival in the recovery room (time 0) patients in the i.v. group received an i.v. infusion of morphine 0.2 ml/kg body weight over 20 min. Mean dose was 12.4 (range 10.2–17.6) mg. Patients in the extradural group received the same i.v. volume of physiological saline solution.

Patients were connected to the PCA device (Prominject, Pharmacia) which was set to deliver a bolus dose of i.v. morphine 0.04 mg/kg body weight whenever the patient pushed the button. The amount of morphine given in a single dose varied from 2–3.5 mg. A lockout time of 10 min was used.

*Table 1* Design of the study

| | I v. group | Extradural group |
|---|---|---|
| 1 | Extradural NaCl 0.15 ml kg$^{-1}$ as bolus dose when peritoneum is closed | Extradural morphine 0 15 ml kg$^{-1}$ (0 06 mg kg$^{-1}$) as bolus dose when peritoneum is closed |
| 2 | Intravenous morphine 0.2 ml kg$^{-1}$ (0.2 ml kg$^{-1}$) after awakening | I v. NaCl 0.2 ml kg$^{-1}$ after awakening |
| 3 | PCA 0.04 mg kg$^{-1}$ bolus dose. Lockout time 10 min | PCA 0.04 mg kg$^{-1}$ bolus dose. Lockout time 10 min |
| 4 | Extradural NaCl 0.15 ml kg$^{-1}$ 6 h after first dose | Extradural morphine 0.15 ml kg$^{-1}$ (0.06 mg kg$^{-1}$) 6 h after first dose |

A second dose of extradural morphine 0.06 mg/kg body weight was given 6 h after the initial dose, and a blinded dose of extradural saline to the i.v. group. The mean cumulative dose of extradural morphine after the second dose was 7.9 (1.2) mg.

Plasma samples were obtained and pain ratings were assessed before the first three episodes of self-administration. These usually occurred during the first 2 h after arrival in the recovery room. Postoperative pain was assessed using a 100-mm visual analogue scale (VAS) where 0=no pain and 100=unbearable pain. Additionally, VAS scores were assessed and arterial blood samples obtained at specific times (0, 0.5, 1, 2, 4, 8, 12 and 18 h, and at 1, 2, 4, 8 and 18 h, respectively, after arrival in the recovery room). Patients spent the night in the recovery room where mobilization is not routine. To evaluate the effects of i.v. and extradural morphine, frequent VAS measurements were made and evaluation of side effects and influence on cognitive functions. VAS assessment on movement and during coughing were not measured as the patients were not mobile.

### ASSESSMENT OF ADVERSE EVENTS

At 4, 8 and 18 h after arrival in the recovery room, staff asked the patients if they experienced any adverse events. If so, they were questioned specifically about the presence of nausea, vomiting, tiredness, vertigo, dry mouth, pruritus, blurred vision and dyspnoea. They were asked to grade symptoms from 0 to 3, where 0=no symptoms, 1=mild, 2=moderate and 3=severe.

### COGNITIVE FUNCTIONS

Two tests of cognitive function were used: the grammatical reasoning test[12] and the letter cancellation test.[13] The grammatical reasoning test evaluates reasoning ability and the letter cancellation test assesses visual search ability, which is measured by speed (number of items covered in 3 min) and correctness (percentage correct) of responses. Both tests were presented to all subjects on four occasions: 1 day before surgery and at 2, 8, and 18 h after arrival in the postoperative unit. The ability to perform both tests varied considerably as a result of incapacity (tiredness), which might be evaluated by compliance rate (percentage of individuals making efforts to solve the tests).

### CLINICAL CARE

We monitored heart rate, systolic and diastolic arterial pressures, and ventilatory frequency every 30 min. Arterial blood-gas tensions were measured at 2, 8 and 18 h after arrival in the recovery room. Patients were given i.v. glucose and balanced electrolyte solutions, approximately 2–3 litre, over 18 h.

### ANALYTICAL METHODS

Blood samples were centrifuged within 1 h. Plasma was transferred into plastic tubes and stored at −20°C until analysis. Plasma concentrations of morphine, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) were assayed in duplicate using high pressure liquid chromatography, as described previously.[14] The method has an STD (inter-day) variability of 7.0%, 4.2% and 3.3% when assaying plasma concentrations of morphine, M3G and M6G, respectively, at therapeutic concentrations. The area under the plasma morphine concentrations *vs* time curve (AUC) (0–18 h) was calculated for each individual.

### STATISTICAL METHODS

The results were tested with Student's *t* test for parametric data and the Mann–Whitney *U* test for non-parametric data. Results are given as mean (SD) or median (range) according to distribution. For repeated measurements the Friedman test was used. For analysis of correlation the Spearman rank test was used. $P<0.05$ was considered significant. The possible differential deleterious effects on cognitive function from the two methods of postoperative pain relief were analysed using a 2 (groups) × 4 (test occasions) ANOVA for each measure.

## Results

There were no differences in age, weight, height or duration of surgery between the groups (table 3). There was a difference in BMI ($P<0.05$) and in perioperative bleeding ($P<0.05$). There were three patients with excessive bleeding. One patient in the i.v. group bled 2100 ml and two patients in the extradural group bled 1400 ml and 1500 ml, respectively. One patient in the i.v. group and six patients of those receiving extradural morphine bled 500–1000 ml. All other patients lost less than 500 ml.

Patients in the extradural group reported lower pain scores than the i.v. group at 4, 8, 12 and 18 h after arrival in the postoperative unit ($P<0.001$) (fig. 1). At 4 and 18 h, mean VAS scores were 9 (SD 11) mm and 9 (13) mm, respectively, in the extradural group. Corresponding values in the i.v. group were 51 (23) mm and 28 (18) mm, respectively. Even though extradural morphine was administered on average 30 min before arrival in the postoperative unit, these patients had as high VAS scores as women treated with i.v. morphine during the initial 1 h (fig. 1). Patients reported no pain on awakening. At 8 h, only two of 20 patients in the i.v. group were pain free (VAS=0) compared with 15 of 20 patients

*Table 3* Characteristics of patients (mean (SD) or range). $^*P<0.05$

| | I.v. ($n$=20) | Extradural group ($n$=20) |

| Mepivacaine (mg) | 378 (14) | 378 (14) |

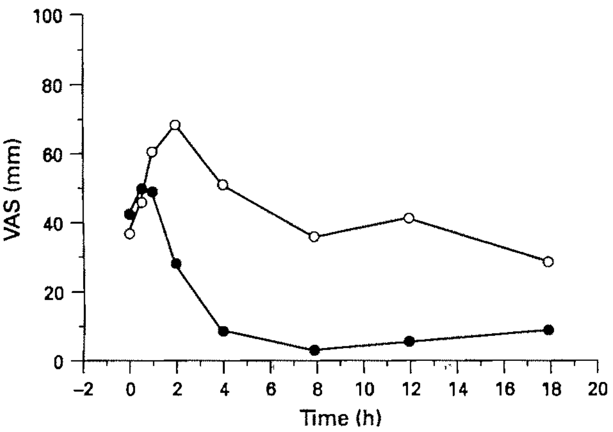

*Figure 1* Mean pain scores (VAS) in the extradural (●, $n=20$) and i.v. (○, $n=20$) morphine groups during the initial 18 h after operation. Time 0=time of arrival in the recovery room.

in the extradural group. The corresponding values at 18 h were two of 20 and 10 of 20, respectively.

There was a difference between groups in the frequency and timing of demand for PCA morphine (fig. 2). The extradural group took only a few doses (mean 6.6 (5.9) (range 0–23) doses) (fig. 2), mostly within 2 h. The i.v. group took morphine repeatedly over 18 h (mean 18 (7.3) (range 7–30) doses) (fig. 2). This difference was significant ($P<0.001$, Mann–Whitney). Consequently, the cumulative dose of morphine at the end of the 18-h study period differed between the two groups (fig. 3). The cumulative dose was 14–105 mg in the i.v. group and 0–55 mg in the extradural group ($P<0.001$, Mann–Whitney). Mean morphine consumption in the i.v. group was 44 (20.8) mg corresponding to 2.4 mg $h^{-1}$ over 18 h. The values were 17.2 (16) mg and 1 mg $h^{-1}$ for the extradural group (fig. 3).

In the i.v. group we found a 10–20-fold variability in plasma morphine concentrations when patients took their three initial i.v. bolus doses of PCA morphine (table 4). Plasma concentrations of M6G before the first, second and third PCA doses showed less variation but increased significantly with time ($P<0.001$, Friedman test) (table 4). Plasma concentrations of morphine in the extradural group were markedly lower at the initial three PCA doses. Interestingly, mean plasma morphine concentrations, before the initial three doses, were consistent in patients in the i.v. group. Plasma concentrations of morphine at fixed intervals in the two groups are presented in figure 4. Concentrations were highest at 1 and 2 h when pain scores were high. There were large inter-individual variations in plasma concentra-

tions, especially in the i.v. group. Morphine concentrations were lower in the extradural group during the whole postoperative period, resulting in mean 18 h AUC values of 1504 (2106) (range 172–9977) nmol h for the i.v. and 497 (577) (range 97–2591) nmol h for the extradural group, respectively ($P<0.001$, Mann–Whitney). We found no correlation between AUC of plasma morphine concentrations and the AUC of VAS in either group over 18 h or any correlation between cumulative consumption of morphine at 18 h and AUC of VAS at 0–18 h.

### SIDE EFFECTS

All patients in each group reported adverse events. Tiredness and dryness of the mouth were frequent in both groups of patients. At 2 and 8 h, all patients in the i.v. group reported mild to severe tiredness and at 18 h only one patient reported no tiredness. In the extradural group ($n=20$), 16–17 patients reported mild to severe tiredness at 2, 8 and 18 h. At 18 h the frequency of itching was 24% and 37% in the extradural and i.v. groups, respectively (ns). The risk of morphine-induced urinary retention could not be measured as all patients had urinary catheters for more than 24 h.

At 18 h after arrival in the recovery room (time 0), cumulative PCA morphine in the i.v. group correlated with intensity of each of the following side effects: tiredness, itching, blurred vision and vertigo ($n=20$ , $P<0.05$ Spearman rank; 0=no symptoms, 1=mild, 2=moderate and 3=severe). In the extradural group tiredness at 18 h correlated with cumulative morphine ($n=20$ , $P<0.05$, Spearman rank). Preoperative $Pa_{CO_2}$ was less than 5 kPa in both groups. At 8 h, mean $Pa_{CO_2}$ was 5.7 kPa in the extradural and 5.6 kPa in the i.v. group, with similar variability within each group. Both groups had a significantly increased $Pa_{CO_2}$ compared with preoperative values ($P<0.001$, Friedman test), but there was no difference between groups (Mann–Whitney).

One patient in the extradural group experienced respiratory depression with increasing $Pa_{CO_2}$ levels up to a maximum of 8.3 kPA at 10 h after the first dose of extradural morphine and 4 h after the second extradural dose. A total of 7.32 mg of extradural morphine had been given to this patient. She had self-administered i.v. morphine on two occasions and had received a total dose of 4.8 mg of i.v. morphine at 10 h. This patient also hypoventilated with decreasing ventilatory frequency but had no signs of apnoea. Her ventilatory frequency was less than 10 bpm on several occasions, but she did not require ventilatory support and administration of naloxone was not necessary.

### COGNITIVE FUNCTIONS

Some patients were too tired to complete the tests (compliance). At 2 h after arrival in the recovery room, 45% in the extradural and 70% in the i.v. group were too tired to complete the tests. The effect of group was not statistically significant for any of the cognitive measures or compliance. But the effect of test occasion was significant for both compliance ($P<0.0001$), speed ($P<0.0001$) and correctness ($P<0.05$) of letter cancellation and for compliance ($P<0.0001$) and correctness of grammatical reasoning ($P<0.001$), but not for speed of grammatical reasoning. There was no interaction between group and test occasion in any measure. There were no significant differences between groups.

### CLINICAL CARE

There were no differences between the extradural and i.v. groups in arterial pressure, heart rate or ventilatory frequency. In both groups several patients had a ventilatory frequency less than 10 bpm but no patient had apnoea.

## Discussion

Our results confirm previous reports on excellent postoperative analgesia from extradural morphine, and support the opinion that the quality of pain relief from extradural morphine is superior to that generated by i.v. morphine administered on demand by patients.[1 9 10 15]

Two doses of extradural morphine gave very good analgesia. During the 18 h after operation, only eight of 20 patients required more than 15 mg of i.v. PCA morphine. However, four of 20 patients required more than 30 mg of i.v. PCA morphine in addition to extradural morphine. Sjöström, Hartvig and Tamsen[16] have shown that a minority of patients take remarkably high PCA doses of extradural morphine in the postoperative period. In their study, hourly consumption of extradural morphine via PCA varied from 0.19 to 1.04 mg. It is not yet known what mechanisms are behind this variability among patients in the need for opioids after extradural morphine administration. During the first 1–2 h in the recovery room, patients in the extradural group had VAS scores of 30–40 mm (fig. 1). The slow onset of analgesia in the extradural group was related to the hydrophilic nature of morphine causing slow diffusion of drug to the site of opioid receptors localized in the dorsal horn of the spinal cord.[2 17]

Despite individualized administration of i.v. morphine, patients in the i.v. group had consistently higher VAS ratings than the extradural group. It seems unlikely that they could have taken more morphine as all patients except one complained of tiredness. A few patients hesitated to use additional PCA doses because of fear of side effects such as vomiting and nausea. This fear proved correct as we found an association between high doses of i.v. opioids and side effects. An infusion longer than 1 min was not feasible to reduce side effects as some patients complained of incomplete pain relief from PCA, especially during the first 2 h after surgery. These patients, in contrast, found the lockout time of 10 min too long. Nevertheless, the i.v. group had mean VAS scores greater than 30 mm during the whole postoperative period. In spite of the i.v. loading dose and our relatively high PCA doses, pain relief was inadequate.

Why did i.v. morphine provide unsatisfactory pain relief after hysterectomy in this study? It has been suggested that various forms of pain (or pain components) are differentially sensitive to the route of administration of opioids. In one study, patients with visceral pain that was inadequately relieved by systemic opioids had pain relief from extradural morphine.[18] As hysterectomy is an abdominal operation there is a somatic (cutaneous and muscular) and a visceral pain component. I.v. morphine and i.v. pethidine had little effect on the visceral components of labour pain whereas the somatic type (back pain) was relieved.[19 20] We suggest that failure of i.v. morphine to provide as good analgesia as extradural morphine can be explained by the fact that i.v. opioids are less efficient in treating visceral pain.[19 20]

We found nine-fold variation in the amount of self administered morphine in the i.v. group over the 18 h after operation. This variation is in accord with results reported by previous investigators.[6 21] Patients in the i.v. group required a mean of 2.4 mg $\text{h}^{-1}$ of morphine. This value is close to that of 2.6 mg $\text{h}^{-1}$ reported by Tamsen and colleagues in middle-aged patients (30–50 yr) undergoing major colon surgery.[5] We also observed marked inter-individual variability in plasma morphine concentrations (more than 10-fold). Mean plasma morphine concentrations decreased slightly from the first to the third self-administered dose (ns). Our results indicate that there are inter-individual differences in sensitivity to morphine. The reason is unknown but could be genetically influenced. There was a significant increase in concentrations of M6G which could explain the decreasing concentrations of mean plasma morphine as M6G contributes to pain relief.[22] The highest plasma concentrations of morphine were seen at 1 and 4 h when VAS scores were high (figs 1, 4).

Even when patients in the i.v. group had high concentrations of morphine (mean 169 nmol $\text{litre}^{-1}$ before the first PCA dose) their pain relief was inadequate (table 4). Dahlström and co-workers estimated 16 ng $\text{ml}^{-1}$ ( equivalent to 56 nmol $\text{litre}^{-1}$) as the minimum analgesic concentration.[6] This value was not confirmed in our investigation where patients had high pain scores even at morphine concentrations greater than 56 nmol $\text{litre}^{-1}$ (table 4). The AUC of morphine concentrations 0–18 h did not correlate with the AUC of VAS, indicating that plasma morphine concentration was not directly influencing the extent of pain relief. Morphine concentrations at 1, 4 , 8 and 18 h, and the AUC of morphine concentrations 0–18 h were significantly lower in the extradural group who nevertheless had superior pain relief. This result is in accord with earlier studies showing that the pain relief from extradural morphine is mainly caused by its effect on receptors in the spinal cord[2] while plasma morphine concentrations are more important for side effects and influence on cognitive functions.[17] Unexpectedly, no differences in cognitive functions were seen between the groups. Cognitive tests for monitoring CNS effects indicated that all patients were affected, especially at 2 h after operation, showing that the tests were sensitive.

There are few studies showing VAS scores within 1 h of awakening after abdominal surgery. In an investigation of pain relief after hysterectomy, VAS scores were 65 mm (mean) in the control group immediately after surgery.[23] There are other studies where VAS scores were 50–65 mm during the first 2 h after surgery.[24–26] We have found no study on abdominal surgery showing VAS scores less than 40 in this early period when parenteral opioids are used for pain relief. These results are similar to ours and suggest that extradural morphine or local anaesthetics have to be administered in advance and before the end of surgery.

## Acknowledgements

Mrs Christina Alm gave considerable help and support during the planning and initial phase of the study. Mrs Birgit Silén assisted with most of the drug analysis. Anette Rickebjer provided expert secretarial assistance.

# Target-controlled infusion of alfentanil for postoperative analgesia: a feasibility study and pharmacodynamic evaluation in the early postoperative period

M. C. O. VAN DEN NIEUWENHUYZEN, F. H. M. ENGBERS, A. G. L. BURM, A. A. VLETTER, J. W. VAN KLEEF AND J. G. BOVILL

**Summary**

We have examined the feasibility of target-controlled infusion of alfentanil (TCIA) and the pharmacodynamics of alfentanil in the early postoperative period. Patients were allocated randomly to one of the three groups to receive balanced anaesthesia with bolus injections of fentanyl (group F), sufentanil (group S) or alfentanil (group A. In the recovery room all patients received the same analgesic regimen, comprising TCIA. To evaluate the efficacy of postoperative analgesia, pain scores were measured on a visual analogue scale (VAS) and patients indicated a need for additional analgesia. EC$_{50}$, the concentration at which, with a 50% probability, patients reported adequate analgesia, was estimated using logistic regression. Six patients did not complain of pain. The time from the last intraoperative bolus injection of opioid until patients complained of postoperative pain was shorter ($P<0.05$) in group A (mean 68 min) than in group F (101 min) and group S (136 min). The time to onset of satisfactory analgesia was comparable in the three groups (median 18 min in group F, 15 min in group S and 14 min in group A). EC$_{50}$ of alfentanil was determined in 28 patients; mean values were 26 ng ml$^{-1}$ (group F), 39 ng ml$^{-1}$ (group S) and 52 ng ml$^{-1}$ (group A). We conclude that TCIA, under the conditions studied, resulted in a fast onset of adequate analgesia, irrespective of the opioid administered during operation. Also, there was no effect of opioids administered during operation on postoperative pharmacodynamics of alfentanil. (*Br. J. Anaesth.* 1997; **78**: 17–23)

**Key words**

Analgesia, postoperative Analgesia, target-controlled. Analgesics opioid, alfentanil. Pain, postoperative Pharmacodynamics, alfentanil. Pharmacokinetics, alfentanil.

The pharmacological properties of alfentanil (fast onset of action, fast distribution and elimination) make this opioid suitable for use in the postoperative period. Alfentanil is administered preferably by continuous i.v. infusion, whereby after operation the infusion rate is adjusted to the patient's requirements. Alfentanil has been used successfully after operation when administered to the patient by a target-controlled infusion (TCI) system.[1-3] A thorough understanding of the pharmacokinetics and pharmacodynamics of the drug used is essential for rational administration of an analgesic by TCI. Previous studies[4-6] have shown that the pharmacokinetics of alfentanil, studied before and after operation, are applicable when implemented in a TCI system used for prolonged postoperative administration.

Previous studies[1 6] using TCIA have been conducted under strictly standardized conditions for surgery and intraoperative medication. The aim of this study was to investigate the feasibility of the TCI system in the early postoperative phase after balanced anaesthesia with different opioids in a wide patient population.

The pharmacodynamics of alfentanil have only been studied using the minimum effective analgesic concentration in the postoperative period. In this study we evaluated the pharmacodynamics of alfentanil in the early postoperative phase. To study the pharmacodynamics of alfentanil we determined the EC$_{50}$, that is the concentration of alfentanil at which, with 50% probability, the patient reported adequate analgesia, using logistic regression, an approach that has been described to define the intraoperative concentration–effect relationships of various opioids. In addition, we examined the predictive performance of the TCI system, implemented with population pharmacokinetic data.[7]

## Patients and methods

After obtaining medical Ethics Committee approval and informed consent, we studied 37 patients, ASA I or II, aged 18–65 yr, undergoing elective general, major orthopaedic or gynaecological surgery under general anaesthesia lasting longer than 1 h. Patients

---

M. C. O. VAN DEN NIEUWENHUYZEN*, MD, F. H. M. ENGBERS, MD, A. G L. BURM, MSC, PHD, A. A VLETTER, BSC, J. W VAN KLEEF, MD, PHD, J. G. BOVILL, MD, PHD, FFARCSI, Department of Anaesthesiology, University Hospital Leiden, Leiden, The Netherlands Accepted for publication· September 19, 1996

*Address for correspondence: Department of Anaesthesiology, University Hospital Leiden, PO Box 9600, 2300 RC Leiden, The Netherlands

with a history of cardiovascular, pulmonary, hepatic or renal disease and patients who had taken opioids in the preceding month were excluded. Patients were allocated randomly to one of three groups. All patients received a TCI of alfentanil for postoperative pain management. Before surgery each patient was instructed on the use of the system and on the use of the visual analogue scale (VAS) for pain scoring.

Premedication comprised temazepam 0.3 mg $kg^{-1}$ orally to the nearest 10 mg, 1 h before surgery. On arrival in the operating room, electrocardiogram electrodes were attached and arterial pressure measured. A cannula was inserted in a large forearm vein. After induction of anaesthesia, a 20-gauge cannula was introduced into a radial artery for arterial pressure monitoring and collection of blood samples. Anaesthesia was maintained with 66% nitrous oxide in oxygen and enflurane (end-tidal concentration 0.2–1.0 %) or isoflurane (end-tidal concentration 0.3–1.0 %). Anaesthesia was supplemented with bolus doses of fentanyl in patients in group F, with bolus doses of sufentanil in patients in group S and with bolus doses of alfentanil in patients in group A. The size of the bolus doses and the timing of intraoperative opioid injections were determined by the responsible anaesthetist, who was not involved in the postoperative part of the study. Bolus dose sizes and times of administration were noted. Pancuronium was given for neuromuscular block. At the end of surgery, the trachea was extubated after the patient had recovered consciousness and when adequate ventilation (ventilatory frequency $>8$ bpm, end-tidal carbon dioxide concentration $<6.5$ vol% and tidal volume $>7$ ml $kg^{-1}$) had been established. After extubation of the trachea the patient was transported to the post-anaesthesia care unit and supplementary oxygen was given routinely.

After operation all patients received the TCI system, which was connected to an i.v. cannula in a large forearm vein. The syringe contained alfentanil 0.25 mg $ml^{-1}$. A computer-controlled infusion pump was used for administration of alfentanil. The computer (Atari Portfolio, Acoustic, Japan) was connected to a syringe pump (Ohmeda 9000, Strector, UK) via a serial RS232 communication channel. The software, written in Pascal by one of the authors, was supplied with population pharmacokinetic data, reported by Maitre and colleagues.[7] The system allowed a theoretical target plasma concentration of alfentanil ($C_T$) to be attained rapidly and maintained. To achieve and maintain $C_T$, the infusion rate was recalculated and changed every 10 s by the computer. Cumulative volumes infused were stored at least every 1 min on a 128 Kb Portfolio memory card and with every change in $C_T$. For safety reasons the maximum infusion rate of the Ohmeda pump was limited to 100 ml $h^{-1}$ (=25 mg $h^{-1}$).

The patient was instructed to report the onset of pain to one of the investigators. At that moment the patient's pain was scored, using a 10-cm VAS, and the degree of sedation was scored using the six-point scale described by Ramsay and colleagues[8]: (1) patient anxious and agitated or restless, or both; (2) patient cooperative, oriented and tranquil; (3) patient responds to commands only; (4) patient asleep, but with a brisk response to a light glabellar tap or loud auditory stimulus; (5) patient asleep, sluggish response to a light glabellar tap or loud auditory stimulus; and (6) asleep, no response.

If the sedation score was $<3$, the TCI system was activated. The initial $C_T$ of alfentanil was 20 ng $ml^{-1}$. After 5 min the patient's sedation and pain scores were assessed and when the patient indicated a need for additional analgesia and the sedation score was $<3$, $C_T$ was increased by 10 ng $ml^{-1}$. These assessments and adjustments were repeated at 5-min intervals until the patient, while oriented (sedation score $<3$), indicated no need for additional analgesia, and had a VAS score $\leqslant 3.0$. When these criteria were met $C_T$ was maintained at the corresponding level. The loading period was ended when the oriented patient requested no additional analgesia, had a VAS score $\leqslant 3.0$ and $C_T$ had not been changed for 30 min. Thereafter, the step size in $C_T$ was decreased to 5 ng $ml^{-1}$ with a lockout period of 5 min.

If the patient did not request additional analgesia during a 10-min period $C_T$ of the computer-controlled infusion was decreased by 5 ng $ml^{-1}$. If 10 min after the new $C_T$ had been reached the patient still had not requested additional analgesia, $C_T$ was again decreased by 5 ng $ml^{-1}$. This procedure was repeated until a request for additional analgesia was made, when $C_T$ was increased by 5 ng $ml^{-1}$, as described above.

Every 5 min VAS score, sedation score and vital signs were documented. No VAS scores were obtained when the patient was asleep. Peripheral oxygen saturation ($Sp_{O_2}$) (Nellcor, Hayward, CA, USA) and heart rate were monitored continuously and a respiration monitor (MR10, Graseby Medical, Watford, UK) constantly recorded ventilatory frequency. Respiratory depression was defined as ventilatory frequency $<8$ bpm and/or $Sp_{O_2}$ $<90\%$ and/or arterial $Pa_{CO_2}$ $>7.3$ kPa. Arterial blood-gas tensions were measured when $Sp_{O_2}$ $<90\%$ or $Pa_{CO_2}$ $>7.3$ kPa.

Postoperative alfentanil consumption and number of rewarded and unrewarded (during the lockout interval) demands were recorded. TCI was stopped if respiratory depression developed or if the patient wished to withdraw from the study. Side effects observed during the postoperative period were noted. The study was ended when the patient was discharged from the post-anaesthesia care unit. Patients had to stay in the post-anaesthesia care unit for at least 2 h. Postoperative analgesia after the study was prescribed by the responsible anaesthetist. For most patients, this was PCA morphine.

After operation arterial blood samples (3 ml) for measurement of plasma concentrations of alfentanil were obtained just before every change in target plasma concentration of alfentanil. A blood sample was also obtained 5 min after a new $C_T$ was achieved. The maximum amount of blood collected was restricted to 250 ml per patient. Plasma was obtained by centrifugation and stored at −20 °C until analysis. A capillary gas chromatographic technique[9] was used to determine plasma concentration of alfentanil. The detection limit was 0.1 ng $ml^{-1}$. The coefficient of variation in the concentration range ($>1$ ng $ml^{-1}$) in this study was $<5\%$.

A logistic regression model was fitted to the inadequate/adequate analgesia data *vs* measured plasma concentration of alfentanil obtained from the three groups. Adequate analgesia was defined as when the patient indicated no need for additional analgesia and had a VAS score $\leq 3.0$. Inadequate analgesia was defined as when the patient indicated a need for additional analgesia or had a VAS score $>3.0$. The logistic regression model is described by the following formula:

$$P=\frac{C_P{}^{\gamma}}{EC_{50}{}^{\gamma}+C_P{}^{\gamma}}$$

where $P$=probability of adequate analgesia, $C_P$=measured plasma concentration of alfentanil, $EC_{50}$=concentration corresponding to 50% probability that patients do not need additional analgesia and have a VAS score $\leq 3.0$ and $\gamma$=dimensionless variable indicating the sigmoidicity of the curve. $EC_{50}$ was considered to be 0 ng $ml^{-1}$ for patients that did not complain of pain during the study.

The predictive performance of the computer-controlled infusion system, implemented with the population pharmacokinetic data set from Maitre and colleagues,[7] was assessed by examining bias and inaccuracy, as described by Raemer and colleagues.[10] Bias is a measure of the systematic failure to achieve the target plasma concentration. Inaccuracy is a measure of the expected failure to achieve the target plasma concentration. Both bias and inaccuracy are aggregated measures of the performance of the system. For each blood sample the performance error (PE) was calculated as:

$$PE=\frac{(C_P-C_{pred})}{C_{pred}}\times 100$$

where $C_P$=measured plasma concentration of alfentanil and $C_{pred}$=corresponding predicted plasma concentration. The bias of the system is expressed as median PE (MDPE) for all blood samples. When 95% confidence intervals of the MDPE included zero, it was concluded that no significant bias had occurred. The system inaccuracy is the median of the absolute values of individual PE values (MDAPE). In addition, MDPE and MDAPE were also calculated for each patient from all blood samples collected from that patient. Data points with $C_T=0$ ng $ml^{-1}$ and $C_P<1$ ng $ml^{-1}$, where $C_T$ is the target plasma concentration of alfentanil, were omitted from this analysis.

For patients in the alfentanil group, the intraoperative alfentanil bolus doses were entered into a computer running a simulation program described by Hull[11] in order to calculate the concentrations of alfentanil in the three compartments at the start of postoperative analgesic therapy. Subsequently, cumulative volumes infused as stored by the computer were used to simulate new alfentanil concentrations as if the intraoperative alfentanil concentration had been taken into account by the computer. These new simulated alfentanil concentrations ($C_{sim}$) were then used to calculate the performance error of the blood samples of patients in the alfentanil group. For patients in the fentanyl and sufentanil groups, intraoperative opioid bolus doses were entered into the computer simulation program IVA-SIM (Schüttler, Kloos, Bonn, Germany) in order to predict the plasma concentration of fentanyl and sufentanil at the moment when the patient complained of pain.

Data were examined for normality using the Shapiro–Wilk test and are presented as mean (SD) or as median and 95% confidence interval (CI) or range, as appropriate. Patient data and variables describing the efficacy of treatment were compared using analysis of variance followed by the Newman–Keuls test, Kruskal–Wallis test or log-likelihood ratio test, as appropriate. Adverse reactions are reported as frequency of occurrence. For each patient, the number of observations with pain scores $>3.0$ were calculated. These numbers were then compared between the three groups using the Kruskal–Wallis test. $EC_{50}$ values were compared between groups using the Kruskal–Wallis test. $P<0.05$ was regarded as the minimum level of statistical significance.

## Results

We studied 37 patients; four patients in the fentanyl group and two in the sufentanil group did not report pain during the 2-h stay in the recovery room.

Data from one patient in the alfentanil group was excluded from analysis because of a surgical complication. Patient data, duration of anaesthesia, intraoperative opioid consumption and postoperative alfentanil consumption in the remaining 36 patients are presented in table 1 and did not differ between groups, except for intraoperative opioid consumption (not tested). No patient needed naloxone to restore adequate ventilation at the end of anaesthesia. All patients were breathing spontaneously on arrival in the post-anaesthesia care unit. As shown in

*Table 1* Patient characteristics, duration of anaesthesia, and intraoperative and postoperative opioid consumption (mean (SD))

| | Fentanyl ($n$=14) | Sufentanil ($n$=12) | Alfentanil ($n$=10) |
|---|---|---|---|
| Age (yr) | 37 | 43 | 42 |
| Weight (kg) | 73 (11) | 78 (16) | 70 (12) |
| Sex (M/F) | 7/7 | 5/7 | 3/7 |
| Duration of anaesthesia (min) | 166 (64) | 203 (63) | 147 (71) |
| Intraoperative opioid consumption (mg) | 0.6 (0.2) | 0.084 (0.036) | 13.2 (10.1) |
| Postoperative alfentanil consumption ($\mu g\ kg^{-1}\ min^{-1}$) | 0.28 (0.21) | 0.31 (0.21) | 0.37 (0.16) |

*Table 2* Onset of postoperative pain and satisfactory analgesia, end of loading period, total observation time and total number of demands (mean (SD) or median (range)). $^*P<0.05$ compared with fentanyl and sufentanil groups. (Patients who did not report pain during the study period are excluded)

table 2, postoperative pain treatment was started sooner ($P<0.05$) after the last intraoperative alfentanil bolus (mean 68 min), than after the last fentanyl (mean 101 min) or sufentanil bolus (mean 136 min). Measured concentrations of alfentanil for patients in group A at the moment they reported pain were 24–97 ng $ml^{-1}$ (median 56 ng $ml^{-1}$). The time after termination of anaesthesia when patients first reported pain did not differ between the three groups: 39 (20) min (group F), 41 (16) min (group S) and 41 (21) min (group A). All but three patients needed another increase in target concentration after the initial step of 20 ng $ml^{-1}$ to achieve adequate analgesia. There were no differences in duration of the loading period, total observation time (from the start of TCIA to the end of study) and total number of demands between the three groups (table 2). There were no unrewarded demands during the study. The number of observations where patients were asleep, awake with pain sores ≤3.0 and awake with pain scores >3.0 are shown in table 3 and did not differ between groups.

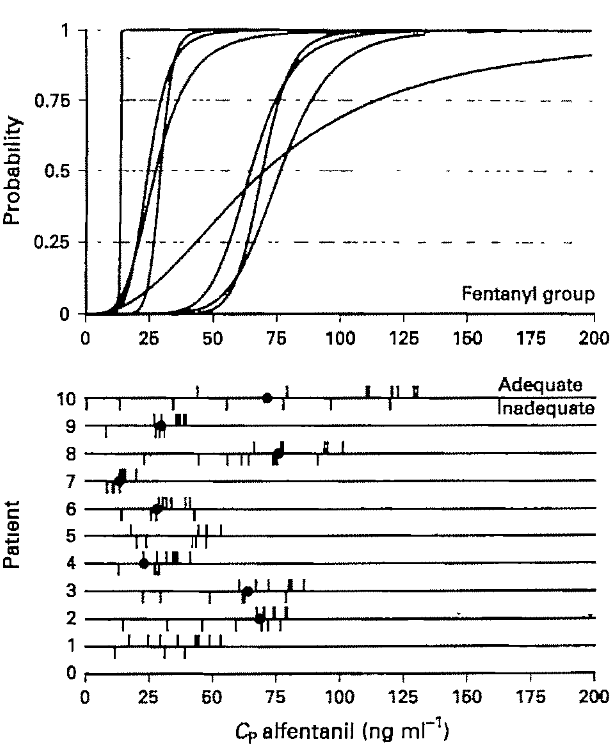

*Figure 1* Relationship between measured plasma concentration of alfentanil ($C_p$) and absence or presence of adequate analgesia in the postoperative period for individual patients in the fentanyl group. The lower panel represents the plasma concentrations of alfentanil and the associated presence or absence of adequate analgesia in patients in the fentanyl group. Adequate analgesia is indicated by an upward deflection, inadequate analgesia by a downward deflection. The $EC_{50}$ value is indicated by the large dot. For four patients who did not complain of pain during the study, $EC_{50}$ was considered to be 0 ng $ml^{-1}$.

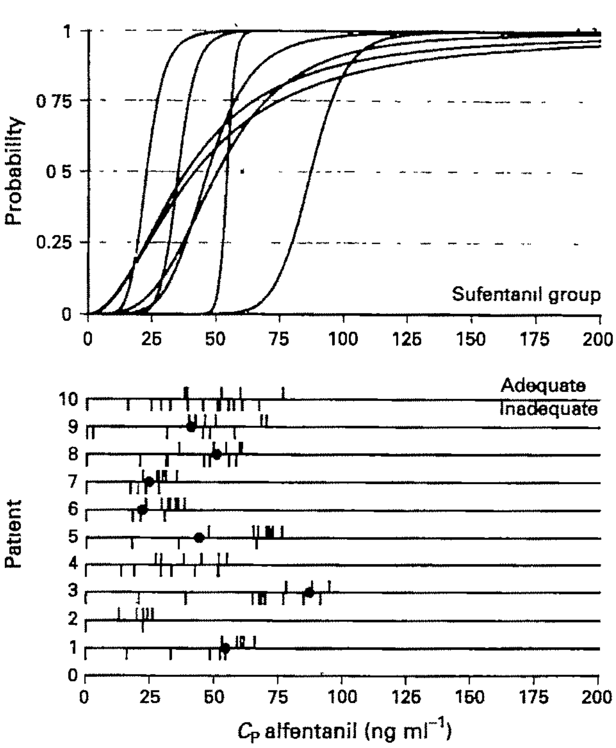

*Figure 2* Relationship between measured plasma concentration of alfentanil ($C_p$) and absence or presence of adequate analgesia in the postoperative period for individual patients in the sufentanil group. The lower panel represents the plasma concentrations of alfentanil and the associated presence or absence of adequate analgesia in patients in the sufentanil group. Adequate analgesia is indicated by an upward deflection, inadequate anelgesia by a downward deflection. The $EC_{50}$ value is indicated by the large dot For two patients who did not complain of pain during the study, $EC_{50}$ was considered to be 0 ng $ml^{-1}$.

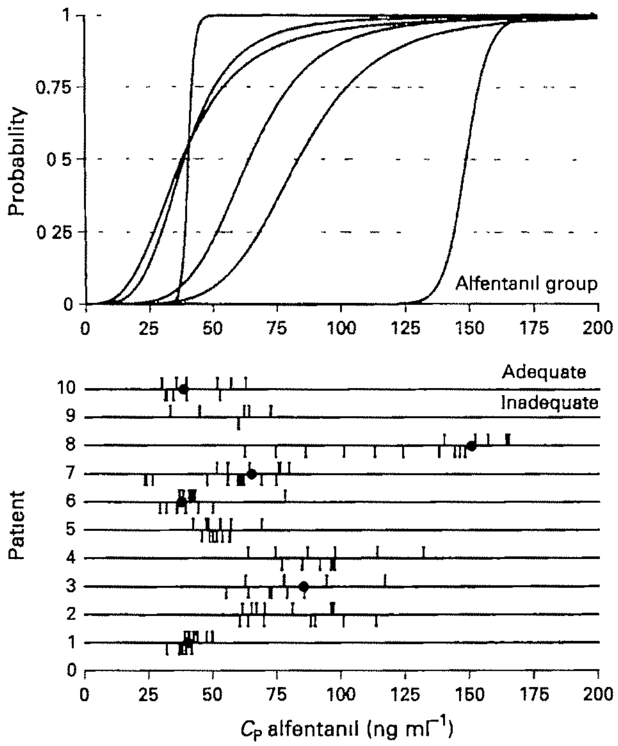

*Figure 3* Relationship between measured plasma concentration of alfentanil ($C_p$) and absence or presence of adequate analgesia in the postoperative period for individual patients in the alfentanil group. The lower panel represents the plasma concentrations of alfentanil and the associate presence or absence of adequate analgesia in patients in the alfentanil group. Adequate analgesia is indicated by an upward deflection, inadequate analgesia by a downward deflection The $EC_{50}$ value is indicated by the large dot.

The alfentanil concentration–effect relationships of individual patients in the three groups are shown in the figures 1–3. The $EC_{50}$ of alfentanil was median 26 ng ml$^{-1}$ (range 0–76 ng ml$^{-1}$) for group F, 39 (0-87) ng ml$^{-1}$ for group S and 52 (38–151) ng ml$^{-1}$ for group A. The $EC_{50}$ values of alfentanil, excluding patients that did not report pain, were 47 (13–76) ng ml$^{-1}$ for group F, 44 (23–87) ng ml$^{-1}$ for group S and 52 (38–151) ng ml$^{-1}$ for group A. The adequate/inadequate analgesia *vs* concentration data for individual patients are displayed underneath the curves. In one patient in group S (patient No. 2) and in one patient in group A (patient No. 9) there was only one observation with inadequate analgesia. The concentration–effect relationship of alfentanil therefore could not be determined in these patients. In two, one and three patients in groups F (patient Nos 1, 5), S (patient No. 10) and A (patient Nos 2, 4, 5), respectively, the model was unable to describe the data because there was too much overlap between adequate and inadequate analgesia. Inspection of the raw data suggested that the $EC_{50}$ of the patients in whom the concentration–effect relationship could not be determined was likely to be in the same range as those of the other patients.

The bias and inaccuracy of the system calculated from all blood samples were, respectively, −1 (95% CI −7 to +7) % and 20 (15–22) % in the fentanyl group, −6 (−14 to 0) % and 21 (18–26) % in the sufentanil group and −2 (−8 to +10) % and 33 (25–37) % in the alfentanil group for the simulated predicted values. As the confidence limits included zero, there was no significant bias.

Ventilatory frequency and postoperative $Sp_{O_2}$ were always within the clinically acceptable range. Sedation score was ≤3 in all patients at all times. No patient developed hypotension, defined as a decrease in arterial pressure of more than 15% from preoperative control values. Four patients in group F, three in group S and three in group A needed an antiemetic for nausea or vomiting. In one patient in group F itching occurred.

## Discussion

The main objective of this study was to evaluate the efficacy of target-controlled infusion of alfentanil during the initial recovery period and at the same time to investigate the pharmacodynamics of alfentanil in individual patients. This study was designed such that the concentration–effect relationship was determined after administration of balanced anaesthesia, as used in clinical practice. The onset of the analgesic effect in the postoperative period depends on the characteristics (distribution, elimination and rapidity of its equilibration between blood and brain) of the drug administered in the postoperative period. Analgesic drugs used in the operating theatre may also affect the patient in the postoperative period. In this study intraoperative anaesthesia was provided by enflurane or isoflurane and nitrous oxide supplemented with fentanyl, sufentanil or alfentanil. As expected, we found that patients experienced postoperative pain significantly faster after the last intraoperative bolus of alfentanil than after fentanyl and sufentanil. However, the three groups did not differ in the time interval from the end of anaesthesia to onset of postoperative pain.

In studies where i.v. infusion regimens of alfentanil have been used for analgesia in the postoperative period, inadequate analgesia and respiratory problems have occurred directly after the start of the regimen.[12 13] To date, limited data are available on the use of TCIA only in the postoperative period. The aim of postoperative pain management is to relieve the patient's pain and to increase comfort. In our opinion the best analgesic regimen results in minimization of painful periods without side effects. To test the TCI regimen in the postoperative phase we therefore chose an initial step of 20 ng ml$^{-1}$ when patients first complained of pain. All but three patients (one from each group) needed another increase in target concentration after the initial step to achieve adequate analgesia. It is possible that in the three patients who did not need a further increase in target concentration, adequate analgesia might have been reached with a target concentration<20 ng ml$^{-1}$. However, none of these three patients had any adverse effects, in particular no respiratory depression. We feel therefore that an initial target concentration of 20 ng ml$^{-1}$ is satisfactory. In a previous study we reported a minimum effective analgesic concentration (MEAC) of alfentanil in the immediate postoperative period of 59 ng ml$^{-1}$.[6] With the regimen used in this study, 60 ng ml$^{-1}$ could be

CP25,789

achieved in 25 min. In this study we did not encounter respiratory depression with a step size of 10 ng ml$^{-1}$ and a lockout time of 5 min during the loading period, irrespective of the intraoperative opioid used.

To study the pharmacodynamics of alfentanil, we defined a quantal effect parameter, which considered pain relief as either adequate or inadequate. The criteria for adequate analgesia were: (1) quality of analgesia, which was adequate when the patient indicated no need for additional analgesia or was asleep and (2) VAS score $\leqslant$3.0. Inadequate analgesia was defined as: (1) activation of the TCI system or (2) VAS scores $>$3.0. We chose a cut-off value of the pain score of 3.0 as patients in a previous study using TCI alfentanil were generally satisfied with the therapy at this score.[1]

Our results showed a variability in individual values of EC$_{50}$ ranging from 0 to 151 ng ml$^{-1}$. These results are in agreement with a study where we reported a median minimum effective analgesic concentration of alfentanil of 59 ng ml$^{-1}$ (range 26–159 ng ml$^{-1}$) at the start of therapy for a group of 20 orthopaedic patients.[6] The wide inter-individual variability is well known from the literature and not surprising considering the different types of surgery and the fact that residual concentrations of drugs used during operation, including volatile anaesthetics, were still present during the study. The EC$_{50}$ values did not differ between the groups. As residual concentrations of opioids administered during operation were present during the study, we anticipated that EC$_{50}$ values in patients who had received fentanyl or sufentanil would have been lower than in patients who had received alfentanil during operation. The simulated plasma concentrations of the three drugs administered during operation at the moment when patients reported pain were, on average, 1.7 ng ml$^{-1}$ (range 0.8–3.0 ng ml$^{-1}$) for the fentanyl group, 0.10 (0.04–0.16) ng ml$^{-1}$ for the sufentanil group and 44 (18–141) ng ml$^{-1}$ for the alfentanil group. These concentrations are similar to the reported MEAC values after i.v. administration of different drugs.[6 14–16] During the 2-h study, plasma concentrations of the three drugs administered during operation decreased. At the end of the loading period the simulated plasma concentration of fentanyl had decreased to 1.2 ng ml$^{-1}$ and that of sufentanil to 0.08 ng ml$^{-1}$. The simulated plasma concentrations for patients that did not report pain during the study were in the same range as the plasma concentrations of the patients that used TCIA. EC$_{50}$ values reported in this study were comparable to MEAC values reported in a study[6] where the patient population was strictly standardized. As the EC$_{50}$ of alfentanil did not differ between the three groups, we could not demonstrate differences in postoperative pharmacodynamics of alfentanil between patients that had received balanced analgesia with different opioids. This does not exclude the fact that opioids administered during operation contribute to postoperative analgesia. However, to quantify the contribution of intraoperative opioids on postoperative analgesia would require much larger patient groups.

The performance error was calculated in order to investigate the applicability of a population pharmacokinetic data set in a TCIA after operation. The population pharmacokinetic data described by Maitre and colleagues[7] were obtained from intraoperative studies and therefore might not be optimal for the postoperative period. As the 95% confidence interval for the MDPE included 0 for all three groups, there was no bias. The inaccuracy resulting from implementation of the population pharmacokinetic data set resulted in acceptable MDAPE values of 20–33%. Therefore, the population pharmacokinetic data set described by Maitre and colleagues[7] can be used in a postoperative TCIA regimen.

In summary, TCIA as a postoperative analgesic technique under the conditions studied (initial target concentration of 20 ng ml$^{-1}$, step size of 5–10 ng ml$^{-1}$ with a lockout time of 5 min) was an acceptable technique with a fast onset of satisfactory analgesia. Irrespective of the opioid administered during operation, inter-individual variability in the postoperative pharmacodynamics of alfentanil was large. However, the TCIA regimen easily overcomes this variability so that all patients are rapidly titrated to adequate analgesia.

# I.v. perioperative ketoprofen in small children during adenoidectomy

E. NIKANNE, H. KOKKI AND K. TUOVINEN

## Summary

We have investigated the analgesic and opioid sparing effect of perioperative i.v. ketoprofen in a randomized, double-blind, placebo-controlled, parallel group study in 164 children, aged 1–7 yr, after adenoidectomy. A standard anaesthetic method was used and all children received fentanyl 1 $\mu g\ kg^{-1}$ i.v. during induction. Children in the ketoprofen group received ketoprofen 1 mg $kg^{-1}$ i.v. after induction of anaesthesia followed by an infusion of ketoprofen 1 mg $kg^{-1}$ over 2 h. Children in the placebo group received 0.9% saline. All children received fentanyl 1 $\mu g\ kg^{-1}$ i.v. as rescue analgesia. In the ketoprofen group less children required postoperative fentanyl (64% *vs* 77%, $P=0.006$) and the total number of fentanyl doses was smaller compared with the placebo group (mean 1.0 (SD 1.1) (95% confidence intervals (CI) 0.8–1.3) *vs* 1.5 (1.1) (95% CI 1.2–1.7), $P=0.012$). Worst pain observed in the postanaesthesia care unit was also lower in the ketoprofen group both at rest ($P=0.028$) and during swallowing ($P=0.001$). There were no difference in the number of adverse reactions between the groups. No serious adverse reactions occurred. (*Br. J. Anaesth.* 1997; **78**: 24–27)

**Key words**
Anaesthesia, paediatric. Pain, postoperative. Analgesics non-opioid, ketoprofen. Analgesia, pre-emptive. Surgery, otolaryngological. Children.

Adenoidectomy is one of the most common surgical procedures in childhood. Frequently it is carried out as a day-case operation and children should be painless and alert when leaving hospital. Opioids provide effective analgesia, but also have known side effects such as emesis, sedation and risk of respiratory depression. This restricts the use of opioids after operation during day-case surgery.

The use of non-steroidal anti-inflammatory drugs (NSAID) has been shown to reduce the need for opioids after operation in children.[1] Ketoprofen is a NSAID with a chemical composition of 2-(3-benzophenyl)-propionic acid.[2] It is available in i.v., i.m., oral and rectal formulations. I.v. administration is the most accurate and the most practical route during general anaesthesia. Ketoprofen has proved to provide good postoperative analgesia in adults.[3] In children, it has been studied as an antipyretic agent.[4]

The aim of this study was to investigate the analgesic and opioid sparing effect of i.v. ketoprofen in children aged 1–7 yr after adenoidectomy.

## Patients and methods

The study was approved by the Ethics Committee of Kuopio University Hospital and the parents of patients gave written informed consent.

We studied 164 patients, ASA I or II, aged 1–7 years, undergoing adenoidectomy (with or without myringotomy, tympanostomy or sinus lavage). Patients were excluded if they had a known allergy to ketoprofen or other non-steroidal anti-inflammatory medication, asthma, kidney or liver dysfunction or haemorrhagic diathesis.

A randomized, double-blind, placebo-controlled, parallel group study design was used. Children were allocated randomly to either the ketoprofen or placebo group. After induction of anaesthesia, children in the ketoprofen group received ketoprofen 1 mg $kg^{-1}$ (Orudis, Rhone- Poulenc-Rorer, Denmark) dissolved in 10 ml of 0.9% saline injected over 10 min i.v. as a loading dose followed by an infusion of ketoprofen 1 mg $kg^{-1}$ dissolved in 40 ml of 0.9% saline over 2 h. The total dose of ketoprofen in the ketoprofen group was 2 mg $kg^{-1}$. Children in the placebo group received 0.9% saline for the loading dose and infusion. All children received fentanyl 50 $\mu g\ ml^{-1}$ i.v. as rescue analgesia if required.

A standard anaesthetic technique was used in all children. Each child was premedicated with diazapam 0.5 mg $kg^{-1}$ orally up to a maximum of 10 mg, 30–45 min before induction of anaesthesia. EMLA cream (Astra, Sweden) was used for venous puncture sites.

Anaesthesia was induced with thiopentone 5–7 mg $kg^{-1}$ and fentanyl 1 $\mu g\ kg^{-1}$ i.v. and tracheal intubation was facilitated with atracurium 0.5 mg $kg^{-1}$. Anaesthesia was maintained with 1–1.2% isoflurane (inspired concentration) and 65% nitrous oxide in oxygen with IPPV. On completion of the procedure neuromuscular block was antagonized with neostigmine 50 $\mu g\ kg^{-1}$ and glycopyrronium 10 $\mu g\ kg^{-1}$. All children received fentanyl 1 $\mu g\ kg^{-1}$ i.v. at induction and no more opioid was allowed during operation.

All children were given 0.9% saline 10 ml kg$^{-1}$ h$^{-1}$ for intraoperative maintenance. The children were transferred to the post-anaesthesia care unit (PACU) for continuous monitoring of vital signs and assessment of pain.

Postoperative pain was assessed by the Maunuksela score.[5] The Maunuksela score is an observer assessment based on mimic, vocalization, movement or rigidity of the limbs and body, response to handling and irritability, together with measured cardiorespiratory variables. In the modified score 0="no pain", 1–3="slight pain", 4–6="moderate pain", 7–9="severe pain" and 10="worst possible pain".

Specially trained research nurses assessed the pain experienced by the child at rest and during swallowing. If the child was in pain (pain score at rest was 3 or more) fentanyl 1 μg kg$^{-1}$ was given i.v. for rescue analgesia. The dose was repeated in 5-min intervals until the child was comfortable. No more than three doses of fentanyl were allowed in 1 h. No other analgesic medication was permitted during the study. The children were monitored closely after each dose of fentanyl in the PACU.

When leaving hospital, pain was assessed by nurses using a 100-mm long visual analogue scale (VAS) (0="no pain" and 100="worst possible pain") at rest and during swallowing.[6] Sedation was assessed at the same time using the 100-mm VAS: 0="full alert" and 100="not arousable". All adverse reactions were recorded and summarized for each patient.

The adenoids were removed using indirect curettization. Haemostasis was controlled with nasopharyngeal packs with or without electrocautery. Surgeons estimated the amount of bleeding using a five-point scale: 1=no bleeding, 2=less than normal, 3=normal, 4=more than normal, 5=profuse.

Based on the results of our earlier study[1] a power calculation determined that a sample size of 79 children per group would be required to demonstrate a 30% reduction in the need for opioids. This gave the study 80% power at a significance level of 0.05. Analysis of variables was performed using the two-tailed Student's *t* test, chi-square test and binominal test. $P<0.05$ was considered statistically significant. Results are presented as mean (SD) (95% confidence interval (CI) or range) where appropriate.

## Results

There were no differences between the two groups in sex distribution, age, weight, height or ASA status (table 1) or in the type of surgery performed (table 2).

I.v ketoprofen 1 mg kg$^{-1}$ bolus during anaesthesia followed by an infusion of 1 mg kg$^{-1}$ over 2 h reduced the number of children requiring supplementary doses of fentanyl. In the ketoprofen group, 51 (64%) children and in the placebo group 65 (77%) children received fentanyl ($P=0.006$). Children in the ketoprofen group received fewer fentanyl doses (1.0 (1.1) (95% CI 0.8–1.3)) than children in the placebo group (1.5 (1.1) 95% CI (1.2–1.7), $P=0.012$) (table 3). The number of children who received either none or only one dose of fentanyl was significantly greater in the ketoprofen (60 (75%)) than in the placebo (44 (52%)) group ($P=0.003$). Those children in the ketoprofen group who received fentanyl as rescue analgesia required slightly fewer fentanyl doses than children in the placebo group, but this was not significant ($P=0.104$). In those children who received fentanyl as rescue analgesia the number of children who received only one dose of fentanyl was significantly less in the ketoprofen group (31 (61%)) than in the placebo group (25 (38%), $P=0.017$) (table 4).

*Table 1* Patient data for the two groups (mean (SD) and [range])

| Mean (SD) | 0.4 (0.9) | 0.4 (0.7) |

in the PACU was lower in the ketoprofen group compared with the placebo group both at rest ($P$=0.028) and during swallowing ($P$=0.001).

When discharged there was no difference in pain scores between the groups. Children in the ketoprofen group were slightly less sedated than children in the placebo group, but this was not significant ($P$=0.099).

In the PACU there was no difference in the frequency of adverse reactions between the groups (table 6). In the ketoprofen group 20 children (25%) and in the placebo group 23 children (27%) had one or more adverse reactions. In the ketoprofen group children had more nausea and vomiting than in the placebo group ($P$=0.018). Somnolence was more frequent in the placebo group than in the ketoprofen group ($P$=0.013). There were no serious adverse reactions and the medication was discontinued in only one patient in the ketoprofen group because of gastrointestinal discomfort during infusion.

The time between operation and first urination was significantly shorter in the ketoprofen group (160 (46) min) than in the placebo group (191 (49) min, $P$=0.001).

There were no significant differences in pain scores if only adenoidectomy or adenoidectomy and one or more of the additional operations were considered.

To assess if the age of the children had any effect on pain scores or the need for rescue analgesia, we divided the groups into three age groups: 24 months or less; 25–48 months and over 48 months. There were no differences between the age groups.

*Table 7* Intraoperative bleeding estimated by the surgeon (*n* (%)). *P*<0.05 (chi-square test) between groups

| | Ketoprofen (*n* = 80) | Placebo (*n* = 84) |
|---|---|---|
| Less than normal | 6 (7) | 9 (11) |
| Normal | 62 (78) | 72 (85) |
| More than normal | 12 (15) | 3 (4) |

The surgeon estimated the amount of intraoperative bleeding using a five-point scale. Twelve (15%) children in the ketoprofen group and three (4%) children in the placebo group were classified as bleeding “more than normal”. Six (7%) children in the ketoprofen group and nine (11%) in the placebo group were classified as bleeding “less than normal”. The difference between the groups was significant ($P$=0.037) (table 7). There were no children in either group who experienced postoperative bleeding which would have required intervention or return to the operating theatre or which would have caused any delay on discharge from hospital.

## Discussion

In this study we showed that intraoperative ketoprofen i.v. followed by constant infusion over 2 h significantly reduced (30% reduction) the need for fentanyl after operation in small children after adenoidectomy. Patients in the ketoprofen group needed significantly less fentanyl doses in the PACU than patients in the placebo group. Also, the number of the children who required fentanyl treatment was significantly smaller in the ketoprofen group than in the placebo group. Further, those children who required fentanyl in the ketoprofen group seemed to require slightly fewer doses than those children in the placebo group. Although this finding was not statistically significant, a tendency was clear. Our data suggest that intraoperative administration of ketoprofen to children reinforces opioid-induced analgesia without increased risk of serious adverse reactions.

Two hours after operation children in the ketoprofen group had significantly less pain than children in the placebo group during swallowing. At rest the ketoprofen group also had less pain, but the difference was not significant. This tendency was not seen 1 h after operation. These results indicate a relatively slow onset of the analgesic effect of i.v. ketoprofen. This has been shown also with other analgesics which act via inhibition of prostaglandin synthesis.[7]

The incidence of adverse reactions in previous studies varied widely from none of significance to approximately 50% of patients.[2] In our study, incidences were 25% in the ketoprofen group and 27% in the placebo group. In the placebo group children experienced somnolence significantly more often after operation than children in the ketoprofen group ($P$=0.013). This can be explained by the more frequent doses of fentanyl in the placebo group compared with the ketoprofen group. In the ketoprofen group children had more nausea and vomiting than children in the placebo group ($P$=0.018). In previous studies the increased frequency of postoperative nausea was associated with concomitant use of NSAID and opioid.[8] There were no serious adverse reactions in this study and in only one patient was the medication discontinued. This patient was a 7-yr-old boy in the ketoprofen group and he experienced gastrointestinal discomfort. His symptoms were alleviated immediately after the medication was discontinued. The incidence and scale of adverse reactions in this study were comparable with other studies with short-term use of NSAID in children.[1, 7]

Transient depression of renal function is a known effect of NSAID.[9, 10] The risk of renal failure is highest in patients with diminished renal perfusion caused by hypovolaemia or hypotension, for example. In this study all children received an infusion of 0.9% saline in the perioperative period. No signs of depression of renal function were seen. The time between operation and first urination was significantly longer in the placebo group than in the ketoprofen group, probably because of the greater degree of sedation in the placebo group caused by the greater doses of fentanyl.

Splinter and colleagues showed that preoperative use of ketorolac 1 mg kg$^{-1}$ increased perioperative bleeding in children with tonsillectomy.[11] We found that a ketorolac dose of 1 mg kg$^{-1}$ was rather high. In previous studies, a dose of 0.5 mg kg$^{-1}$ and even a dose of 0.2 mg kg$^{-1}$ had a good analgesic effect after major surgery in children.[7] In our study perioperative bleeding was estimated by the surgeon and was greater in the ketoprofen group than in the placebo group. In all children haemostasis was maintained with nasopharyngeal packs with or without electrocautery. None of the children experienced post-operative bleeding which required intervention or delay in discharge from hospital.

In day-case surgery in children it is important that parents feel safe to leave the hospital with their child. Therefore, a child should be as painless and as alert as possible. In this study children had minimal pain and low sedation scores when discharged. However, there was a tendency for children in the ketoprofen group to be even more alert and have less pain than children in the placebo group.

In this study we used ketoprofen 1 mg kg$^{-1}$ during general anaesthesia and an infusion of 1 mg kg$^{-1}$ after operation for 2 h. Ketoprofen has been shown to have a good antipyretic effect at an oral dose of 0.5 mg kg$^{-1}$ but the effect was significantly better with a dose of 1 mg kg$^{-1}$.[4] Further investigations are needed to find an optimal i.v. ketoprofen dose for children in the treatment of postoperative pain.

# Effect of clonidine on gastric emptying of liquids

T. ASAI, C. MCBETH, J. I. M. STEWART, J. WILLIAMS, R. S. VAUGHAN AND I. POWER*

**Summary**

We have investigated the effects of clonidine on gastric emptying of liquids in 30 patients. In a double-blind, randomized design, clonidine 150 μg, morphine 10 mg or saline in 1 ml was given i.m. One hour later, the patient drank a paracetamol solution (1.5 g in 50 ml water). Venous blood samples were obtained every 15 min for 90 min thereafter. Plasma paracetamol concentrations were measured using high-pressure liquid chromatography and the area under the concentration–time curve was calculated. The degree of sedation and complications were recorded. The area under the curve for 0–60 min was significantly smaller in the morphine group than in the saline group ($P$=0.002; 95% confidence interval (CI) for difference −1237 to −502 μg min ml$^{-1}$), whereas it was greater in the clonidine group compared with the saline group, although this was not significant (95% CI for difference −423 to 1264 μg min ml$^{-1}$). Arterial pressure was significantly lower in the clonidine group compared with the saline group. Both clonidine and morphine appeared to cause mild sedation. We conclude that clonidine 150 μg i.m. does not delay gastric emptying of liquids in a similar manner to morphine. (*Br. J. Anaesth.* 1997; **78**: 28–33)

**Key words**

Gastrointestinal tract, emptying. Sympathetic nervous system, clonidine. Pharmacology, clonidine.

Delay in gastric emptying may induce nausea and vomiting which may increase the risk of pulmonary aspiration of gastric contents during the perioperative period. It may also delay absorption of orally administered drugs. In critically ill patients whose lungs are ventilated mechanically, delay in gastric emptying causes bacterial overgrowth in the gastrointestinal tract and increases the incidence of pulmonary infection.[1] Opioids, which have been used widely for premedication, markedly delay the rate of gastric emptying.[2–4]

Alpha$_2$ adrenoceptor agonists, such as clonidine, reduce anxiety, induce sedation and possibly produce analgesia.[5 6] They decrease the requirements for opioid and inhalation agents during induction and maintenance of anaesthesia and provide haemodynamic stability.[5 6] Alpha$_2$ agonists also produce less respiratory depression, nausea and vomiting, or pruritus than opioids.[5 6] Thus the use of $\alpha_2$ adrenoceptor agonists as adjunctive agents has received considerable attention.

The effects of $\alpha_2$ agonists on gastric emptying have been studied, but the results are inconclusive.[7–11] In some studies in rodents, $\alpha_2$ adrenoceptor agonists injected subcutaneously did not delay gastric emptying of liquids,[7–9] whereas in other studies the agonists delayed emptying.[10 11] In humans, oral clonidine did not significantly delay gastric emptying of radiolabelled solid food,[12] whereas lidamidine, which is also considered as an $\alpha_2$ adrenoceptor agonist, delayed gastric emptying of solid food.[13]

The rate and mechanism of gastric emptying differ considerably for liquids and digestible solids.[14 15] The effect of $\alpha_2$ adrenoceptor agonists on gastric emptying of liquids in humans has not been studied. The main aim of this study therefore was to examine the effect of clonidine on gastric emptying of liquids in humans.

## Patients and methods

In a double-blind, randomized design, before induction of anaesthesia, we studied 30 patients (ASA I or II) undergoing routine gynaecological surgery. Patients with a history of gastrointestinal, heart, hepatic and renal disease were excluded. Patients in whom systolic arterial pressure was either greater than 160 mm Hg or less than 100 mm Hg, or had a heart rate less than 60 beat min$^{-1}$, and those receiving any other medications or with a history of allergic reaction to any drug were excluded. The local research Ethics Committee approved the study and written informed consent was obtained from all patients.

Patients were asked not to eat solid food for at least 5 h and not to drink liquids for 2 h before the start of the study. No premedication was given. Approximately 3 h before induction of anaesthesia,

*Present address: Department of Anaesthesia and Pain Management, Royal North Shore Hospital, University of Sydney, St Leonards, NSW 2065, Australia.

the patient was transferred to a quiet area in the recovery room. An electrocardiograph and non-invasive arterial pressure monitor were attached to the patient. A large-gauge i.v. cannula was inserted under local anaesthesia into the antecubital fossa for blood sampling. Patients were asked to stay in a semi-recumbent position throughout the study.[16] They were also asked to refrain from drinking, eating and smoking.

Patients were allocated randomly to one of three groups. Block randomization (in blocks of 12) was used for allocation and cards indicating allocations were placed in serially numbered, sealed opaque envelops: clonidine group, clonidine 150 μg in a volume of 1 ml; morphine group, morphine 10 mg in a volume of 1 ml; saline group, saline 1 ml.

One anaesthetist prepared the study drug shortly before the start of the study. The second anaesthetist injected the test drug into the anterolateral aspect of the thigh muscle. Both the second anaesthetist and patients were unaware of the randomization.

Gastric emptying was assessed by measuring the plasma concentrations of paracetamol after oral ingestion.[17 18] One hour after injection of the test drug, 50 ml of water containing paracetamol 1.5 g were given orally. We decided that the time from injection of the test drug to ingestion of paracetamol solution should be 1 h, because both the plasma concentration and analgesic effect of i.m. clonidine are maximal at about 1 h.[19] Venous blood (10 ml) was obtained every 15 min for 90 min after ingestion. Each blood sample was placed immediately in an individual tube containing heparin. Plasma was obtained using a centrifuge (CS-15R Centrifuge, Beckman) with a speed of 3000 $\text{min}^{-1}$ for 10 min; temperature in the centrifuge was set as 4 °C. Plasma was stored at $-20$ °C until paracetamol concentrations were measured.

Plasma paracetamol concentration was measured using high-pressure liquid chromatography.[20] The sensitivity of the chromatographic method was 0.1 $\mu g\ ml^{-1}$ of plasma paracetamol. The intra-assay coefficient of variation, that is the precision of the assay for quality control samples prepared at 5, 10 and 50 $\mu g\ ml^{-1}$, was less than 3%. The inter-assay coefficient of variation, that is the accuracy of the assay for the same quality control samples, was less than 5%.

The degree of sedation was examined before, and at 1 and 2.5 h after administration of the test drug. The degree of sedation was scored as follows: 1=awake, 2=drowsy or sleeping, easy to arouse by verbal contact, 3=asleep, difficult to arouse, 4=asleep, not arousable. Any incidence of vomiting, pruritus or dryness of mouth was also recorded.

Arterial pressure and heart rate were monitored throughout. If systolic arterial pressure decreased by more than 30% of the pre-injection value, crystalloid fluid in a volume up to 500 ml was given. Fluid was infused through another i.v. cannula which was inserted into the other arm to avoid possible dilution of the blood sample for paracetamol assay. If arterial pressure was still low, incremental doses of ephedrine 3 mg i.v. were given. If heart rate decreased to less than 45 beat $\text{min}^{-1}$, atropine 0.6 mg was given. If either ephedrine or atropine, or both, were given, patients were withdrawn from the study.

### STATISTICAL ANALYSIS

Median maximum plasma paracetamol concentration ($C_P$max), time to maximum concentration ($tC_P$max), area under the concentration–time curve (AUC) and 95% confidence interval (CI) for each value were calculated. The area was calculated based on the trapezoidal rule.[21]

Hypothesis tests were used only for AUC. Normal plots (plots of normal scores) and Shapiro–Francia $W'$ test[21] showed that the data were normally distributed; however, the $F$ test showed that the variability between the three groups was significantly different. Therefore, the Kruskal–Wallis test was used to compare AUC values between groups. If this proved significant, the Mann–Whitney $U$ test was used to compare AUC between the clonidine and saline groups, and between the morphine and saline groups. $P$ values were adjusted for ties. $P<0.05$ was considered significant.

Differences between two groups in AUC, $C_P$max and $tC_P$max were described by medians and 95% confidence intervals (CI). CI values for medians were calculated using the Sinterval command (sign test) in Minitab Release 8.2, which shows a confidence level close to 95%.

Mean arterial pressure and heart rate at 1 and 2.5 h after administration of the test drug were expressed as difference from pre-injection values. The maximum difference was also obtained. The 95% CI for differences between two groups were calculated.

There is no apparent criterion to decide the clinically relevant difference in AUC between the control and test groups. In one study, in which the same dose of paracetamol in the same volume of water was used as in this study (1.5 g in 50 ml), morphine 10 mg i.m. decreased $\text{AUC}_{0\text{-}90\ \text{min}}$ by 59%.[4] We considered that a reduction in AUC by a test drug of 50% would be a clinically relevant difference. To detect this reduction, with a power of 0.9 and $P=0.05$, approximately eight patients in each group were required.[21 22] We considered that smaller changes in AUC could be assessed using 95% CI. Therefore, we decided to study 30 patients, expecting withdrawal of a few patients from the test groups because of possible complications.

## Results

Ten patients were allocated to the saline group, 11 to the morphine group and nine to the clonidine group. One patient, in whom morphine had been given, vomited shortly after ingestion of the paracetamol solution. Data from this patient were not used for analysis. In two patients in the clonidine group, it was not possible to obtain the blood sample at 90 min because the patient was transferred to the anaesthetic room. Age, weight and height of the patients were similar in the three groups (table 1).

Morphine 10 mg i.m. significantly delayed gastric emptying, whereas clonidine 150 μg i.m. did not

*Table 1* Patient characteristics (mean (SD) [range])

| | Saline group ($n$=10) | Clonidine group ($n$=9) | Morphine group ($n$=11) |

*Table 3* Baseline systolic arterial pressure and heart rate, change from baseline values at 60 and 150 min after administration of the test drug, and minimum values (mean (SD) [95% confidence intervals]). Differences between groups (clonidine – saline or morphine – saline groups) are also shown. The test drug was injected i.m. immediately after obtaining baseline values: saline, clonidine 150 μg or morphine 10 mg in 1 ml. Paracetamol was given at 60 min. *Data at 150 min were from seven patients

| | | Change from baseline | | |
|---|---|---|---|---|
| | Baseline (0 min) | 60 min −0 min | 150 min −0 min | Minimum value −0 min |
| Systolic arterial pressure (mm Hg) | | | | |
| Saline group ($n$=10) | 123 (13) | −7 (11) | −5 (9) | −12 (11) |
| Clonidine group ($n$=9*) | 124 (14) | −13 (14) | −16 (9) | −22 (8) |
| Morphine group ($n$=10) | 121 (12) | 1 (13) | −3 (9) | −9 (7) |
| Differences between groups for changes from baseline | | | | |
| Clonidine – saline | | −6 [−18, 6] | −12 [−20, −3] | −10 [−19, 0] |
| Morphine – saline | | 7 [−3, 18] | 2 [−7, 10] | 3 [−6, 12] |
| Heart rate (beat min$^{-1}$) | | | | |
| Control group ($n$=10) | 72 (5) | 4 (9) | 2 (14) | −1 (9) |
| Clonidine group ($n$=9*) | 74 (10) | 1 (9) | 0 (11) | −6 (9) |
| Morphine group ($n$=10) | 80 (8) | −1 (6) | −2 (7) | −6 (6) |
| Differences between groups for changes from baseline | | | | |
| Clonidine – saline | | −2 [−12, 7] | −2 [−14, 10] | −4 [−13, 4] |
| Morphine – saline | | −5 [−13, 2] | −4 [−14, 7] | −5 [−12, 2] |

(fig. 1, table 2). One-way analysis of variance showed that the AUC value was significantly different between the three groups ($P<0.001$); it was significantly smaller in the morphine group compared with the saline group ($P=0.002$; 95% CI for difference −1237 to −502 μg min ml$^{-1}$). In contrast, although AUC was greater in the clonidine group than in the saline group, this was not statistically significant (95% CI for difference −423 to 1264 μg min ml$^{-1}$).

Both arterial pressure and heart rate before injection of the test drug were similar in the three groups (table 3). Arterial pressure decreased in all the groups after injection of the test drug and was significantly lower after injection of clonidine than after saline (table 3). In one patient in whom clonidine had been given, arterial pressure decreased by more than 30%. Arterial pressure, however, returned to baseline values shortly after infusion of crystalloid fluid 500 ml. Changes in heart rate were not clinically significant (table 3).

*Table 4* Number of patients who were sedated before, and 60 and 150 min after administration of the test drug. The degree of sedation, if present, was always mild (score 2: see text) *Data at 150 min were from seven patients

| | Before | 60 min | 150 min |
|---|---|---|---|
| Saline group ($n$=10) | 0 | 1 (10%) | 4 (40%) |
| Clonidine group ($n$=9*) | 0 | 5 (56%) | 4 (57%) |
| Morphine group ($n$=10) | 0 | 3 (30%) | 7 (70%) |

Both clonidine and morphine appeared to have sedative effects. The degree of sedation, when present, was always mild (score 2) (table 4). The incidence of dryness of mouth was greater in the morphine group (eight patients (73%)) than in either the saline or clonidine groups (three patients in each group). Two patients in the morphine group had pruritus.

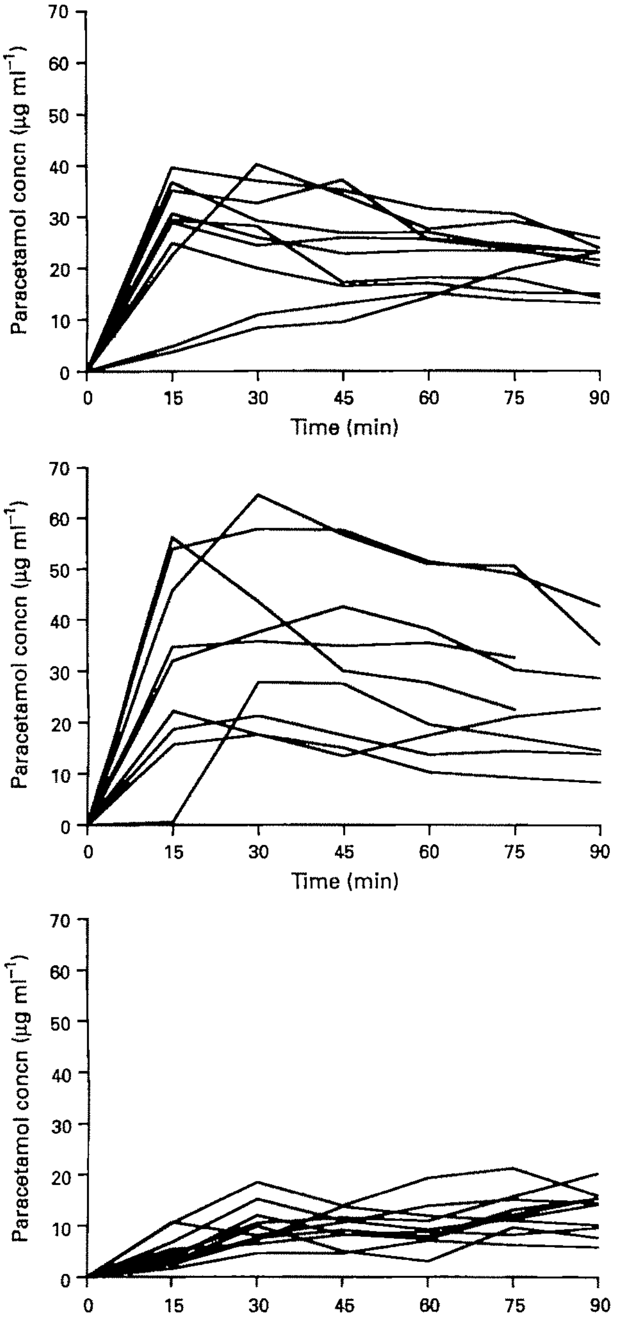

*Figure 1* Individual plots of plasma paracetamol concentration *vs* time after ingestion of paracetamol 1.5 g in 50 ml of water in the saline (top), clonidine (middle) and morphine (bottom) groups.

## Discussion

We have shown that clonidine 150 μg i.m. did not delay gastric emptying of liquids as did morphine. The median plasma paracetamol concentration in the clonidine group was greater than the upper 95% confidence limit of the median concentration in the saline group (fig. 1, table 2).

It was somewhat surprising to see higher plasma concentrations in some patients who had received clonidine. Alpha$_2$ adrenoceptor agonists inhibit contraction of the stomach caused by stimulation of cholinergic neurones,[23 24] although they do not inhibit contraction induced by exogenous acetylcholine.[23] However, they either have no effect or may have a stimulatory effect on the basal tone of the stomach.[24 25] In addition, $\alpha_2$ adrenoceptor agonists inhibit contraction of the pylorus.[26–28] In contrast, opioids increase pyloric pressure[29 30] which impedes emptying of gastric contents into the intestine.[31] Therefore, it might be possible that clonidine increased gastric emptying whereas morphine delayed it.

Paracetamol is not absorbed from the stomach but is well absorbed from the upper small intestine. It has been shown that there is a good correlation between the rate of absorption of paracetamol given orally and gastric emptying of liquids measured by a radio-isotope method.[17] Thus the rate of absorption of paracetamol indicates the rate of gastric emptying.[17 18] However, several factors, other than the rate of gastric emptying, may affect plasma paracetamol concentration.

First, if absorption of liquids from the small intestine is increased, the increase in plasma paracetamol concentration may be enhanced. In the isolated membrane of either the ileum or colon, $\alpha_2$ adrenoceptor agonists increase net transport of both fluid and electrolytes from the mucosal to the serosal side.[32 33] In intact animals, when secretion from the intestine is stimulated by chemical stimulation, $\alpha_2$ adrenoceptor agonists inhibit hypersecretion.[33 34] However, it is not clear if these drugs increase absorption of liquids, electrolytes and drugs from the small intestine during the unstimulated state in intact animals. In addition, opioids also increase absorption of liquids from the small intestine.[35–37]

Second, several factors affect hepatic enzyme activity and influence elimination of paracetamol that is metabolized by the liver: sex differences, ethnic differences, anticonvulsants, antituberculosis drugs, contraceptive pills and pregnancy.[38–43] It is not known if clonidine affects elimination of paracetamol. However, clonidine, about 50% of which is metabolized by the liver,[44] decreases elimination of sulphobromophthalein or bupivacaine from the liver and increases plasma concentrations.[45 46] Therefore, it is possible that clonidine interferes with elimination of paracetamol.

The decrease in arterial pressure after administration of clonidine might also have directly affected gastric emptying, or alternatively, might have decreased elimination of paracetamol by decreasing hepatic blood flow, leading to higher plasma paracetamol concentrations. In this study, the mean decrease in arterial pressure in the clonidine group was less than 20% compared with the saline group (table 3); in one patient in the clonidine group, arterial pressure decreased by more than 30%, but the duration of the decrease was short. In addition, calcium-channel blocking agents, at doses which would decrease arterial pressure, did not affect gastric emptying in humans, although arterial pressure was not measured in any study cited.[47–49] Therefore, the effect of this factor is likely to be minimum.

It seems reasonable to conclude that although the increase in plasma paracetamol concentration after administration of clonidine could have been caused by factors other than increased gastric emptying, it is unlikely that clonidine markedly delayed gastric emptying. Nevertheless, caution is required when the effect of either a test drug or conditions on gastric emptying is interpreted by differences in plasma paracetamol concentrations between groups, in particular when the difference is small.

Clonidine and morphine appeared to provide mild sedation. After administration of clonidine, patients became calmer, suggesting a possible anxiolytic effect of the drug. Morphine caused the well-known undesirable effects, such as vomiting, dryness of mouth and pruritus. In contrast, the incidence of these complications after clonidine was either less or none.

One of the concerns of the use of $\alpha_2$ adrenoceptor agonists as premedication or analgesia is hypotension. Arterial pressure decreased significantly after administration of clonidine but generally the decrease was either mild or moderate. The reference intervals represent the estimated range of values that include a certain percentage of the values among the population.[21] The 95% reference interval (mean±1.96) for the minimum arterial pressure after clonidine was 95–110 mm Hg. Although arterial pressure decreased by more than 30% in one of nine patients in our study, infusion of crystalloid fluid restored the pressure to baseline. Arterial pressure was within the normal range in this study; it is not known if clonidine markedly decreases arterial pressure more frequently in patients with hypertension or hypotension.

# Effect of temperature during cardiopulmonary bypass on gastric mucosal perfusion

N. D. CROUGHWELL, M. F. NEWMAN, E. LOWRY, R. D. DAVIS JR, K. P. LANDOLFO, W. D. WHITE, J. L. KIRCHNER AND M. G. MYTHEN

**Summary**

The purpose of our study was to prospectively study the splanchnic response to hypothermic and tepid cardiopulmonary bypass (CPB) using alpha-stat management of arterial blood-gas tensions. Twenty-four patients for elective CABG surgery were allocated randomly to tepid (35–36 °C) or hypothermic (30 °C) bypass groups. Measurements were made at four times: (1) baseline, (2) stable during CPB (inflow temperature=nasopharyngeal temperature) 30 °C for hypothermic patients, bypass +20 min for tepid patients, (3) 10 min before the end of bypass, (4) after bypass, skin closure. Both groups demonstrated a significant reduction in gastric intramucosal pH (pH$_{im}$) from time 1 to time 4 and there was no difference in the incidence of a low pH$_{im}$ between the tepid and cold groups (4/12 *vs* 3/12; ns) at time 4. pH$_{im}$ was significantly lower in the tepid group at time 3 ($P$=0.03) but this discrepancy may have been because of an artefactually high pH$_{im}$ in the cold group. There was a significantly higher incidence of postoperative non-cardiac complications in patients who had a low pH$_{im}$ at time 4 ($P$=0.0008) Therefore, we conclude that although the temperature during CPB had a transient effect on pH$_{im}$ it is unlikely to be a major determinant in the pathogenesis of gut mucosal hypoperfusion after bypass. (*Br. J. Anaesth.* 1997; **78**: 000–000)

**Key words**

Gastrointestinal tract, pH. Gastrointestinal tract, mucosal perfusion. Heart, cardiopulmonary bypass. Surgery, cardiovascular Temperature, effect.

Despite advances in surgical technique, cardiopulmonary bypass (CPB) and anaesthetic management, non-cardiac complications occur frequently after surgery that requires CPB.[1] Global measures of oxygen consumption and delivery are not reliable predictors of regional organ dysfunction. Indirect measurement of gastric intramucosal pH (pH$_{im}$) is being used as a monitor of a tissue bed that is extremely sensitive to reduced peripheral perfusion and may be important in the pathogenesis of multiple organ dysfunction syndrome (MODS). An abnormally low pH$_{im}$ is common after CPB and a sensitive indicator of a poor outcome. The pathogenesis of the observed decrease in pH$_{im}$ remains poorly defined.

Hypothermia during cardiopulmonary bypass is thought to provide protection from ischaemic injury during CPB. The use of hypothermia during CPB has fallen out of favour in many institutions which has raised concerns regarding the potential for increased ischaemic injury in poorly perfused organs (e.g. the gut) during warm CPB. As a result, the purpose of our study was to prospectively compare the effect of hypothermic with tepid CPB on gastric mucosal pH.

## Patients and methods

After obtaining local Ethics Committee approval and informed consent, we studied 24 patients undergoing elective CABG surgery; patients were allocated randomly to a tepid (35–36 °C) or cold (30 °C) bypass group. Premedication comprised oral diazepam 0.1 mg kg$^{-1}$, oral methadone hydrochloride 0.1 mg kg$^{-1}$ and oral ranitidine 150 mg, 90 min before induction of anaesthesia. Anaesthesia was induced with midazolam 50–100 μg kg$^{-1}$ and fentanyl citrate 5–10 μg kg$^{-1}$, and maintained with a continuous infusion of midazolam 0.5 μg kg$^{-1}$ min$^{-1}$ and fentanyl 0.05 μg kg$^{-1}$ min$^{-1}$ throughout the study. Pancuronium was given as needed to maintain complete neuromuscular block.

Immediately after induction of anaesthesia a tonometer (Tonometrics Division Instrumentarium Corp., Helsinki, Finland) was inserted into the stomach and its position confirmed by injection of air down the nasogastric tube while auscultating over the epigastrium. The tonometer was primed for each measurement with 2.5 ml of 0.9% saline. The $P$CO$_2$ of the lumen of the stomach was measured indirectly by sampling the saline in the gas-permeable silicone

balloon on the end of the tonometer after an equilibration period of more than 30 min and analysing the aspirate in a blood-gas analyser. At the same time an arterial sample was obtained to measure arterial bicarbonate concentration. $pH_{im}$ was calculated by inserting the values of gastric tonometer $P\text{CO}_2$ and arterial bicarbonate into a modified Henderson–Hasselbalch equation (eqn (1)), as described and validated previously.[2 3]

$$pH_t = 6.1 + \log_{10}(\text{arterial } [HCO^-{}_3] / P\text{CO}_2 (\text{tonometer}) \times K)$$

where $K$=time-dependent equilibration constant provided by the manufacturer. Measurements were made at four times: (1) baseline (before aortic cannulation); (2) stable during CPB (inflow temperature=nasopharyngeal temperature) 30 °C for cold patients, bypass +20 min for tepid patients; (3) before the end of bypass; and (4) after bypass, skin closure.

The perfusion apparatus consisted of a Cobe CML oxygenator (Cobe Laboratories, Lakewood, CO, USA) and a Sarns 7000 max pump (Sarns Inc, Ann Arbor, MI, USA). Non-pulsatile perfusion of 2.4 litre $\text{min}^{-1}$ $\text{m}^{-2}$ was maintained throughout the study. The pump was primed with a colloid and crystalloid solution designed to achieve a packed cell volume (PCV) of 0.18 or higher during extracorporeal circulation. Packed red blood cells were added when necessary to achieve the desired PCV. All patients underwent CPB with an ascending aortic cannula, an arterial filter and single stage venous cannula included in the system.

Blood-gas and tonometer saline analyses were made with a BGE IL1400 blood-gas electrolyte analyser (Instrumentation Laboratories, Lexington, MA, USA). Oxygen saturation and haemoglobin measurements were made on an IL482 co-oximeter (Instrumentation Laboratories, Lexington, MA, USA). Arterial carbon dioxide tension was maintained throughout CPB at 4.8–5.3 kPa (uncorrected for body temperature) and $Pa_{O_2}$ at 20–32 kPa.

Data management and analysis were performed using the SAS statistical system, version 6.08 for Windows on a 486-66 mHz Insight pc. All data were examined for normality of distribution, and group comparisons were made using parametric $t$ tests or non-parametric Wilcoxon rank sum tests as appropriate; descriptive data are presented as mean (SD). For comparisons of patient data, Wilcoxon's rank sum test of group equality was used. Cardiovascular variables were analysed by overall repeated measures analysis of variance followed by pairwise comparisons with baseline within groups (paired $t$ test) and also between groups (Wilcoxon rank sum test). $P<0.05$ was considered significant, without adjustment for multiple comparisons in the follow-up descriptive comparisons.

## Results

There was no difference between the hypothermic ($n$=12) and tepid ($n$=12) groups in patient characteristics, duration of bypass or aortic cross-clamp time (table 1). In the primary repeated measures analysis, there was no overall significant difference between the two groups in any of the cardiorespiratory variables, haemoglobin or $pH_{im}$ (table 2, fig. 1). Our sample size of 24 (12 per group) gave 80% power to distinguish a significant difference in $pH_{im}$ as small as 0.066 or larger between the groups.

In the follow-up descriptive comparisons there was a significant difference between the two groups in mean arterial pressure (MAP) at time 1 and nasopharyngeal temperature at times 2 and 3. Both groups demonstrated a significant increase in tonometer $P\text{CO}_2$ and a decrease in $pH_{im}$ from baseline to time 4. The increase in tonometer $P\text{CO}_2$ was independent of arterial $P\text{CO}_2$ which was unchanged in both groups. $pH_{im}$ was significantly lower in the tepid group at time 3 ($P$=0.03). The cold group had

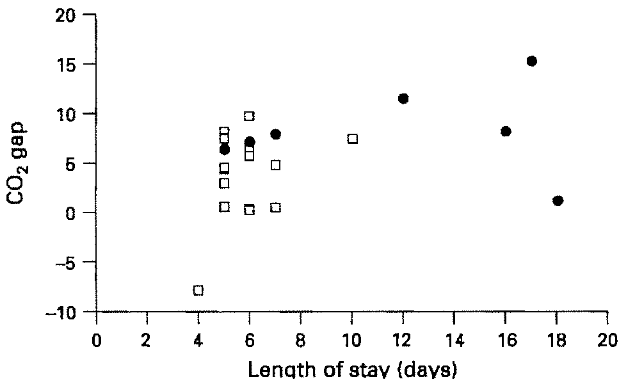

*Figure 2* Duration of hospital stay related to carbon dioxide ($CO_2$) gap and $pH_{im}$. $CO_2$ gap is the gap between gastric luminal $P\text{CO}_2$ and arterial $P\text{CO}_2$. Gastric hypercapnia relative to arterial $P\text{CO}_2$ is indicative of gut mucosal hypoperfusion. $pH_{im}$ is calculated by substituting gastric $P\text{CO}_2$ and arterial bicarbonate measured from arterial blood-gas analysis into a modified Henderson–Hasselbalch equation (see patients and methods). Logistic regression analysis examining the association between $pH_{im}$ (as a continuous measure) and risk of postoperative complications demonstrated a significant relationship ($P=0.0008$) between $pH_{im}$ at time 4 and prolonged hospital stay

a significant increase in base deficit compared with baseline at times 3 and 4. In both groups there was a significant decrease in haemoglobin concentration over time. Seven patients had an abnormally low $pH_{im}$ ($\leq 7.32$) by time 4. There was no difference in the incidence of a low $pH_{im}$ between the two groups (four in the cold group compared with three in the tepid group).

Of the seven patients who had a low $pH_{im}$ at time 4, four developed postoperative non-cardiac complications that resulted in an increased (greater than 7 days) duration of stay in hospital (table 3). One patient in the group that had a normal $pH_{im}$ at the end of surgery had an increased length of hospital stay. Logistic regression analysis, testing association between $pH_{im}$ (as a continuous measure) and risk of postoperative complications, demonstrated a significant relationship ($P=0.0008$) between $pH_{im}$ at time 4 and prolonged hospital stay (fig. 2).

## Discussion

This is the first prospective randomized study comparing gastric mucosal perfusion using tepid and cold bypass. The results indicate that the reduction in gastric mucosal perfusion after cardiac surgery was independent of the temperature during CPB. The warm group had a significantly lower $pH_{im}$ at time 3 during CPB. This was not evident after rewarming. The results of this study are consistent with previous studies that reported that decreases in gastric mucosal $pH_{im}$ are common after cardiac surgery and associated with prolonged hospital stay[2 4–7]

Kutilla, Niinikoski and Haglund examined the relationship between gastric $pH_{im}$ and peripheral tissue perfusion in patients after admission to the intensive therapy unit after hypothermic CPB.[8] They found that $pH_{im}$ decreased steadily over 4 h as the patient's core temperature increased to normal. From 4 to 8 h after operation, $pH_{im}$ increased again to normal. Over the same 8-h period they recorded a steady improvement in peripheral perfusion, as judged by subcutaneous and transcutaneous tissue oxygen tension, laser Doppler skin red cell flux and finger tip temperature, all measured on the same arm. They found no change in central haemodynamic state (including cardiac output). They attributed the changes to redistribution of blood flow after hypothermic CPB. Landow and colleagues studied patients during CPB to determine the relationship between gastric $pH_{im}$ and several other more invasively derived indices of splanchnic perfusion.[9] They found that mean $pH_{im}$ increased during the period of hypothermic CPB and then became abnormal only after rewarming. Gastric $pH_{im}$ correlated with hepatic venous lactate concentration and hepatic venous oxygen, suggesting supply-dependent oxygen deficit across the splanchnic bed. They proposed that with rewarming after hypothermic cardiopulmonary bypass there is regional oxygen consumption/delivery mismatch. This could have occurred in our patients and this postulate is consistent with our own $pH_{im}$ data in the hypothermic group. In a canine model, Ohri and colleagues demonstrated that during the rewarming phase of CPB there was jejunal mucosal hypoperfusion in spite of an increase in local blood flow.[10] They proposed a shunting phenomenon where blood flowed freely in the serosal but not mucosal layers. All of these studies suggest that temperature change is an important factor in the pathogenesis of gut mucosal hypoperfusion after CPB. Our results do not support this hypothesis because after cardiopulmonary bypass there was a significant decline compared with baseline but no difference between the two temperature groups.

Previous studies have suggested that the decrease in gastric pH to abnormal values is in proportion to the duration of CPB.[9 11] Suggested causes of impaired gut perfusion on CPB include occult hypovolaemia, ingestion of environmental endotoxin and release of endogenous vasoconstrictors during CPB.[6 12 13] During CPB large quantities of angiotension II are released.[14] In animal models, angiotension II was found to be a potent selective splanchnic vasoconstrictor.[15] Cardiopulmonary bypass also causes activation of platelets, neutrophils and inflammatory pathways.[16] Resulting microaggregate formation may cause microvascular occlusion and local reduction in oxygen delivery.[17] We have demonstrated previously that pre-emptive plasma volume expansion with a starch solution significantly reduces (but does not eliminate) gut mucosal hypoperfusion after bypass.[7] We have also noted that higher concentrations of endogenous endotoxin antibodies confer some protection against activation of inflammatory pathways and gut mucosal hypoperfusion.[18] Other investigators have tried to improve gut mucosal perfusion in the post-bypass period using cardioactive drugs such as dopexamine and dobutamine.[19] Despite increasing both whole body and splanchnic oxygen delivery, these drugs failed to improve gastric mucosal perfusion, as judged by the persistence of a low pH$_{im}$. One suggestion was that persistence of a gastric mural acidosis in the face of increased oxygen delivery was because of serosal shunting of blood in response to rewarming after cold CPB. We now believe that this is unlikely and think that microvascular occlusion secondary to formation of microaggregates or emboli is more consistent with the currently available data, as suggested in a study of retinal microembolism.[17]

The changes in pH$_{im}$ noted during hypothermic CPB in this and other studies may be artefactual as no allowance was made in the tonometric technique for the effects of temperature on carbon dioxide production, solubility and diffusion through tissues and the tonometer balloon. The tonometric technique is dependent on both aerobic and anaerobic production of carbon dioxide. The main reason for deliberately cooling patients during CPB is to reduce tissue metabolic rate and thus aerobic carbon dioxide production. Although this has not been studied systematically it seems reasonable to assume that background carbon dioxide production is reduced proportionally to temperature reduction and this calculated pH$_{im}$ is increased artefactually, independent of gut perfusion. In addition, reducing temperature increases tissue solubility of carbon dioxide and decreases diffusion through both tissues and the tonometer balloon. The manufacturers state that the device is intended for determination of "intramucosal pH of the gastric mucosal tissue at 37 °C". All of these factors would tend to give a falsely higher pH$_{im}$, irrespective of perfusion of the gastric mucosa. The possible artefactual effects of hypothermia on the tonometric readings have been poorly validated and are worthy of further investigation. This is a potential limitation of the interpretation of time 2 and 3 measurements in this study; however it should not affect conclusions drawn of the effect from beginning to end of CPB measurements.

There has been much recent debate on the validity of the calculation of pH$_{im}$ from gastric luminal $P\mathrm{CO}_2$ and systemic arterial bicarbonate.[6 20 21] Calculated pH$_{im}$ can be influenced by systemic acid–base disturbances independent of splanchnic perfusion. It has been suggested that a more specific measure of gut perfusion is the gap between gastric luminal $P\mathrm{CO}_2$ and arterial $P\mathrm{CO}_2$. Gastric hypercapnia relative to arterial $P\mathrm{CO}_2$ is indicative of gut mucosal hypoperfusion. In this study the significance of the results comparing the two groups was unaltered using calculated pH$_{im}$ or arterial to gastric $P\mathrm{CO}_2$ gap. However, one patient who had a poor outcome had an increased carbon dioxide gap but a normal pH$_{im}$ while another had a low pH$_{im}$ but a normal gap (fig. 2). Again, the significance of the results was unaltered but underlines the current suggestion of changing from calculation of pH$_{im}$ to reporting carbon dioxide gap. Calculated pH$_{im}$ is a sensitive indicator of tissue hypoperfusion whereas the carbon dioxide gap is a more specific indicator of gastric hypoperfusion.

The approach to arterial blood-gas management during hypothermic CPB remains controversial. In studies comparing pH and alpha-stat management, pH-stat management produced greater cognitive dysfunction after bypass, especially in patients requiring longer bypass times.[22 23] However, there are no human data comparing the two techniques in gut perfusion. It is the practice in our institution to use alpha-stat management of arterial blood-gas tensions.

The complications reported (table 3) occurred in patients in whom a low pH$_{im}$ developed. These data are consistent with the hypothesis that gut mucosal hypoperfusion may result in translocation of endotoxin, additional activation of inflammatory pathways and subsequent end-organ dysfunction.

We conclude that splanchnic hypoperfusion is common after CPB and associated with prolonged hospital stay. There was a lower pH$_{im}$ during warm CPB; this may have been because of an artefactually high pH$_{im}$ in the cold group. After CPB, using alpha-stat management of arterial blood-gas tensions, there was a significant reduction in pH$_{im}$ in both groups and the incidence of a low pH$_{im}$ and major complications were the same in both groups. Therefore, we conclude that temperature during CPB had no significant effect on the degree of gut mucosal hypoperfusion after CPB.

# Non-invasive measurement of cerebral blood volume in volunteers

A. K. GUPTA, D. K. MENON, M. CZOSNYKA, P. SMIELEWSKI, P. J. KIRKPATRICK AND J. G. JONES

**Summary**

Invasive techniques are used for conventional measurements of cerebral blood volume and there is a need for methods which are more readily applicable clinically. We studied 13 healthy volunteers using near infrared spectroscopy and transcranial Doppler sonography. Middle cerebral artery flow velocity (vmca) and changes in cerebral oxygenated haemoglobin ($HbO_2$), deoxygenated Hb (Hb), $HbO_2$+Hb (Hbdiff) and $HbO_2$+Hb (total haemoglobin; Hbt) were measured at baseline and during graded reduction in arterial oxygen saturation ($Sp_{O_2}$) to 85%, at hypo-, normo- and hypercapnia. Cerebral blood volume (CBV) values, calculated from regression lines of Hbdiff/$Sp_{O_2}$ and $HbO_2$/$Sp_{O_2}$ were 5.38 and 4.03 ml 100 $g^{-1}$ for the two methods, respectively. CBV varied directly with $FE'_{CO_2}$, with mean CBV reactivities of 1.25 and 1.06 ml 100 $g^{-1}$ $kPa^{-1}$, respectively. Changes in Hbt were not systematically related to changes in $FE'_{CO_2}$. An increase in vmca and reciprocal decrease in estimated cerebrovascular resistance were observed when oxygen saturation decreased to less than 90–93%. These results suggest that cerebral haemodynamics in *individual* subjects may be monitored non-invasively providing the methodology is modified to account for hypoxic vasodilatation. (*Br. J. Anaesth.* 1997; **78**: 39–43)

**Key words**

Hypoxia. Brain, blood flow. Brain, blood volume. Measurement techniques, near infrared spectroscopy

Changes in arterial oxygen and carbon dioxide tensions have important effects on the cerebral vasculature. Hyperventilation is commonly used to reduce cerebral blood volume (CBV) and control increased intracranial pressure during neuroanaesthesia and in neurosurgical critical care. While several studies have addressed the effects of changes in $Pa_{CO_2}$ on cerebral blood flow, few have addressed the effects of carbon dioxide changes on CBV because methodology for its measurement is not available widely and not applicable to routine monitoring of individual patients in clinical practice.

The aim of this study was to evaluate the use of non-invasive methods to estimate CBV using graded arterial hypoxaemia and changes in carbon dioxide tension. Changes in cerebral blood flow and CBV were estimated by non-invasive methods of monitoring using transcranial Doppler (TCD)[1] and near infrared spectroscopy (NIRS), a relatively new application of an existing technology which can be used to provide information on changes in the levels of cerebral oxygenated and deoxygenated haemoglobin, cerebral blood flow and volume.[2–9]

## Subjects and methods

After obtaining local research Ethics Committee approval and informed consent, we studied 13 healthy subjects (eight men), mean age 35 (range 22–57) yr.

The middle cerebral artery (MCA) was localized through the temporal window with the TCD probe (SciMed, Bristol, UK) and the sample depth volume altered until the trunk of the MCA was being insonated. This provided time-averaged mean measurements of MCA flow velocity (*v*mca). The NIRS probes (NIR 1000; Hammamatsu Photonics, Japan) were then attached to the forehead, 6 cm apart, on the same side as the TCD and secured by gauze wrapped around the head to prevent movement and interference from extraneous light. We used NIRS to measure cerebral concentrations of deoxygenated haemoglobin (Hb), oxygenated haemoglobin ($HbO_2$), the difference between oxygenated and deoxygenated haemoglobin (Hbdiff) and total haemoglobin ($Hb+HbO_2$). A plethysmographic non-invasive continuous arterial pressure monitor (Finapres; Ohmeda, UK) and a pulse oximeter probe (Multinex; UK) were attached to the fingers on the right hand. Fractional end-tidal carbon dioxide concentrations in expired air ($FE'_{CO_2}$) were measured using an infrared carbon dioxide analyser (Capnomac; Datex, UK).

After a period of stable baseline recording the subject was then asked to breathe air through a mouthpiece connected to a low resistance anaesthetic

breathing system. After 3 min of baseline measurement, the subject was then given a hypoxic mixture of nitrogen in oxygen to gradually decrease oxygen saturation to 85%. After another 3 min of recording at baseline, carbon dioxide was added to the inspired gas mixture to increase the end-tidal carbon dioxide concentration to approximately 1.5 kPa above baseline at normoxia. Steady levels of hypercapnia were maintained for 3 min, after which the hypoxic mixture was re-introduced to gradually reduce $Sp_{O_2}$ to 85% during hypercapnia. Carbon dioxide was withdrawn from the inspired gas mixture, $Sp_{O_2}$ was allowed to normalize and the subject was then asked to hyperventilate aiming for an end-tidal carbon dioxide of 3.5 kPa. Each subject was held at stable hypocapnia for 3 min during which gradual desaturation was again repeated. After this, subjects breathed air until baseline $Sp_{O_2}$ and end-tidal carbon dioxide concentrations were re-established. The measured variables, oxygen saturation, end-tidal carbon dioxide, cerebral oxygenated and deoxygenated haemoglobin concentrations, CBV, arterial pressure and heart rate were averaged over 2-s epochs, down-loaded on to a lap-top computer and analysed using software developed for monitoring intracranial pressure and waveform analysis.[10] An example of the data output from one volunteer is shown in figure 1. As near infrared spectroscopy measures changes in cerebral haemoglobin from baseline values, negative values can appear on the display. When comparing data between individuals, values need to be indexed relative to baseline.

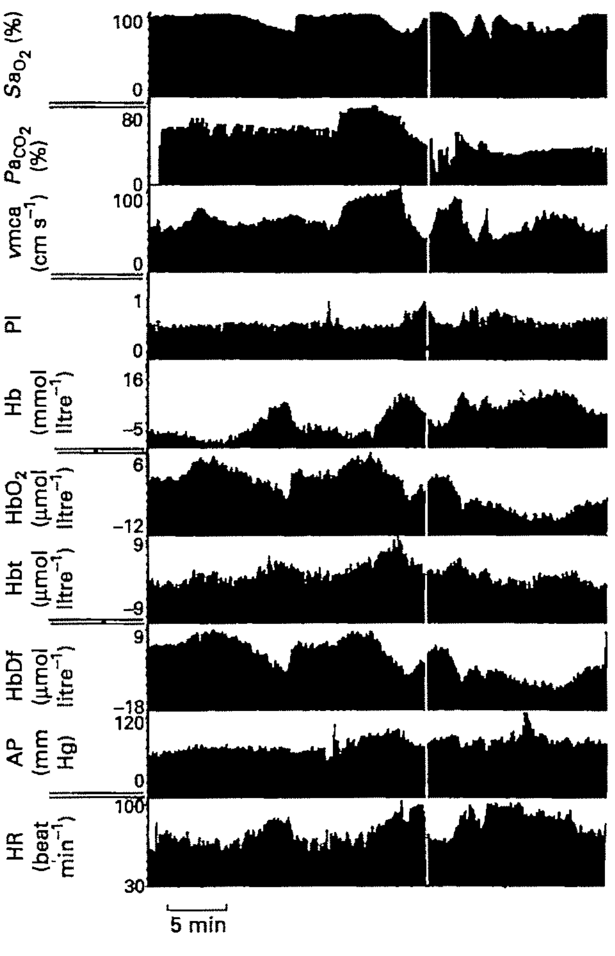

*Figure 1* Summary of part of the multichannel data download in an individual volunteer. $Sa_{O_2}$=arterial oxygen saturation; $Pa_{CO_2}$=end-tidal carbon dioxide concentrations; *v*mca=time averaged mean MCA flow velocity; PI=pulsatility index; Hb=deoxygenated haemoglobin; $HbO_2$=oxygenated haemoglobin; Hbt=total haemoglobin, HbDf=$HbO_2$ – Hb; AP=mean arterial pressure; HR=heart rate.

Regression lines of cerebral oxygenated haemoglobin $HbO_2$ and Hbdiff *vs* oxygen saturation ($Sp_{O_2}$) were plotted for each individual at the three carbon dioxide concentrations, and a value for the slope of $HbO_2/Sp_{O_2}$ calculated. Cerebral haemoglobin ($[Hb_{calc}]$) concentration was calculated using the formula described by Elwell and colleagues[9]:

$$[Hb_{calc}] \text{ (mmol litre}^{-1}) = \Delta[HbO_2]/\Delta Sp_{O_2}$$

The use of the Hbdiff value for this calculation increases the signal-to-noise ratio, but modifies the equation as follows:

$$[Hb_{calc}] \text{ (mmol litre}^{-1}) = \Delta[\text{Hbdiff}]/2 \times \Delta Sp_{O_2}$$

CBV was calculated from this using the following formula:

$$\text{CBV (ml 100 g}^{-1}) = K[\text{Hbcalc}]/Hb \times \text{CLVHR}$$

where *Hb*=large vessel haemoglobin concentration (assumed to be 15 g dl$^{-1}$). Haemoglobin concentration was not measured in individual subjects as all volunteers were healthy adults. This should have no effect on calculated values after indexing the data. CLVHR=Coefficient of the large to small vessel packed red cell ratio (assumed to be 0.69)[9] and *K*=a constant:

$$K = MW_{Hb} \times 10^{-3}/d_t \times 10$$

where $MW_{Hb}$=molecular weight of haemoglobin and $d_t$=tissue density.

Pooled data from all subjects were used to derive regression lines for the relationships between $FE'_{CO_2}$ and absolute CBV, and $FE'_{CO_2}$ and indexed CBV (indexed to calculated CBV at an $FE'_{CO_2}$ of 5.3kPa for each subject). Values of each variable were pooled for all subjects and plotted against $FE'_{CO_2}$ and a regression equation obtained. Regression lines with values less than 0.7 were not included. The slope of the regression line equalled carbon dioxide reactivity of CBV for the group. The second regression equation allowed expression of CBV reactivity as a percentage of baseline CBV, and compensated the contributions of individual variations in baseline CBV to variations produced in CBV reactivity. CBV reactivity was also calculated directly by indexing the change in Hbt to the change in $FE'_{CO_2}$.

The effect of changes in $FE'_{CO_2}$ on *v*mca was assessed by calculating *v*mca at an $FE'_{CO_2}$ of 5.3kPa for each subject, and indexing changes in *v*mca to this value.

## Results

Changes in mean arterial pressure during the course of these experiments were well within the limits of pressure autoregulation (MAP range 71–112 mm Hg). Steady state levels of $FE'_{CO_2}$ at normocapnia, hypercapnia and hypocapnia were achieved in nine of 13 subjects (mean 5.0 (SD 0.32), 6.3 (0.52) and 3.5 ( 0.32) kPa, respectively). Four subjects did not achieve steady state end-tidal carbon dioxide concentrations at one or more stages of the study and

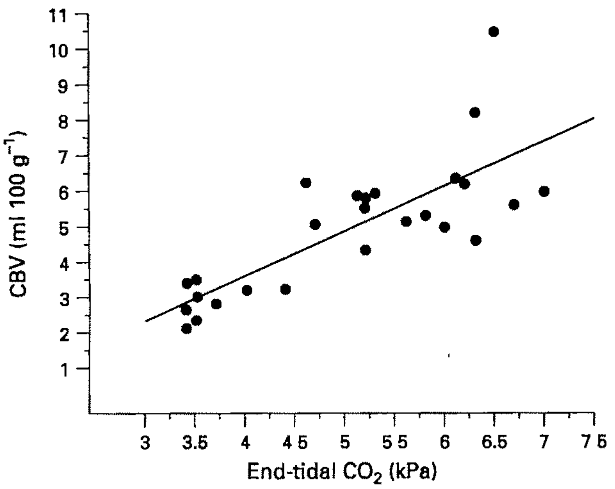

*Figure 2* Cerebral blood flow (CBV) calculated from the slope of Hbdiff *vs* $Sp_{O_2}$ during gradual arterial desaturation to 85%, in relation to $F\mathrm{E}'_{CO_2}$ values for all subjects. The regression equation for the relationship is CBV (ml 100 $g^{-1}$)=1.33+1.25 $F\mathrm{E}'_{CO_2}$ (kPa) ($r^2$=0.06, *P*=0.0001).

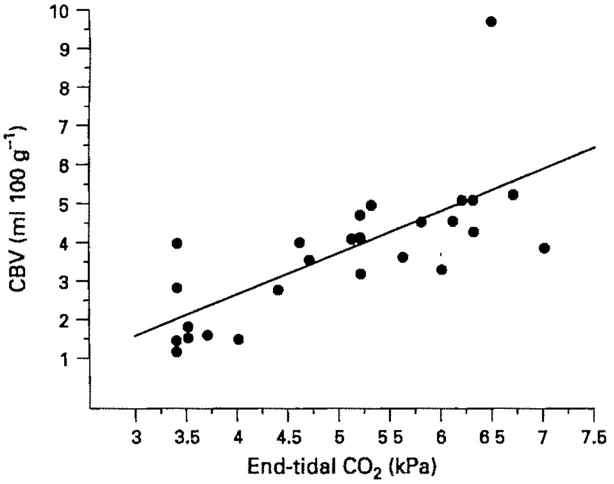

*Figure 3* Cerebral blood flow (CBV) calculated from the slope of $HbO_2$ *vs* $Sp_{O_2}$ during gradual arterial desaturation to 85%, in relation to $F\mathrm{E}'_{CO_2}$ values for all subjects. The regression equation for the relationship is CBV (ml 100 $g^{-1}$)=−1.61+1.06 $F\mathrm{E}'_{CO_2}$ (kPa) ($r^2$=0.51; *P*=0.0001)

were excluded. Data presented here are therefore from nine volunteers.

There were no significant or systematic differences in Hbt concentrations at normal levels of $Sp_{O_2}$ between any of the groups, and changes in Hbt were not significantly related to alterations in $F\mathrm{E}'_{CO_2}$.

CBV values were calculated from the $HbO_2/Sp_{O_2}$ and Hbdiff/$Sa_{O_2}$ regression slopes, and termed CBV(Hbdiff) and CBV($HbO_2$), respectively. CBV calculated by both methods was significantly related to $F\mathrm{E}'_{CO_2}$ ($r^2$=0.60 and 0.51, respectively; *P*<0.0001 for both), equating to CBV reactivities of 1.25 ml 100 $g^{-1}$ $kPa^{-1}$ (95% confidence interval (CI)= 0.8–1.7 ml 100 $g^{-1}$ $kPa^{-1}$) and 1.06 (95% CI=0.61–1.52) ml 100 $g^{-1}$ $kPa^{-1}$, respectively (figs 2 and 3). Mean calculated CBV values at $F\mathrm{E}'_{CO_2}$=5.3 kPa for the two methods were 5.38 (95% CI 5.12–5.64) ml 100 $g^{-1}$ and 4.03 (3.73–4.33) ml 100 $g^{-1}$, respectively. When changes in CBV with $F\mathrm{E}'_{CO_2}$ were indexed to calculated CBV at normocapnia ($F\mathrm{E}'_{CO_2}$=5.3 kPa) for each subject, there was a significant increase in the quality of fit for the regression line of CBV *vs* $F\mathrm{E}'_{CO_2}$ ($r^2$=0.67 and 0.66; *P*<0.0001, respectively) suggesting that at least some of the variability in CBV reactivity was the result of differences in baseline CBV (figs 4 and 5). CBV reactivities calculated from these figures suggested that CBV changed 22% and 25% from normocapnic values for each kPa change in $F\mathrm{E}'_{CO_2}$.

Compared with baseline values at normocapnia, mean *v*mca changed by 18 (14–21)% of normocapnic *v*mca for each kPa change in $F\mathrm{E}'_{CO_2}$ (fig. 6).

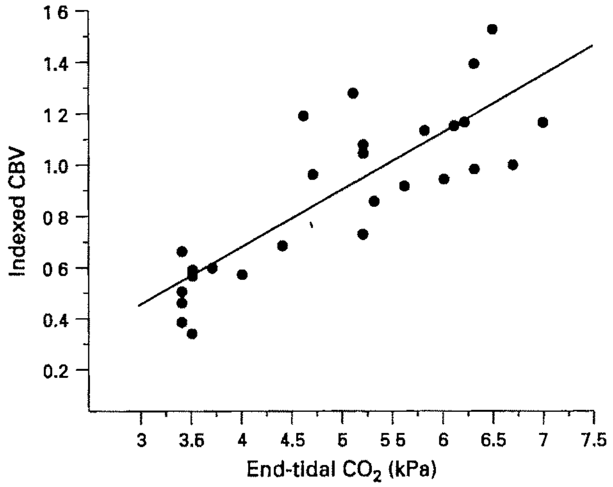

*Figure 4* Cerebral blood flow (CBV) calculated from the slope of Hbdiff *vs* $Sp_{O_2}$ during gradual arterial desaturation to 85%, in relation to $F\mathrm{E}'_{CO_2}$ values for all subjects. Regression equations were obtained for data from each individual subject and the CBV at normocapnia ($F\mathrm{E}'_{CO_2}$=5.3 kPa) calculated. All values of CBV were indexed to this value. The resulting line shows an improvement in fit ($r^2$=0.60 *vs* 0.67) and implies a 22% change in normocapnic CBV values for each kPa change in $F\mathrm{E}'_{CO_2}$

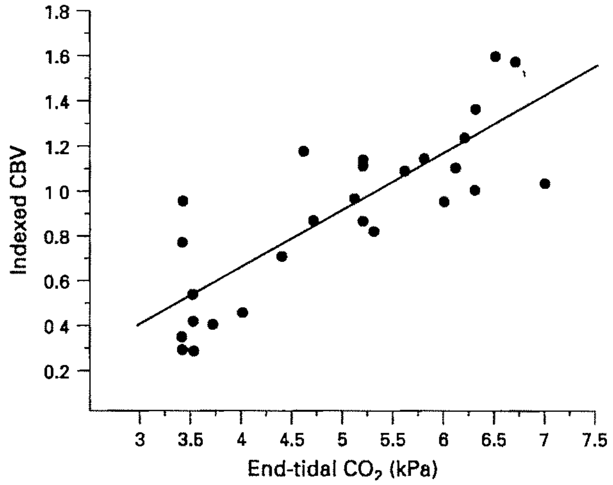

*Figure 5* Indexed cerebral blood flow (CBV) CBV calculated from the slope of $HbO_2$ *vs* $Sp_{O_2}$ during gradual arterial desaturation to 85%, in relation to $F\mathrm{E}'_{CO_2}$ values for all subjects Regression equations were obtained for data from each individual subject and the CBV at normocapnia ($F\mathrm{E}'_{CO_2}$=5.3kPa) calculated. All values of CBV were indexed to this value. The resulting line shows an improvement in fit ($r^2$=0.51 *vs* 0.66) and implies a 25% change in normocapnic CBV values for each kPa change in $F\mathrm{E}'_{CO_2}$.

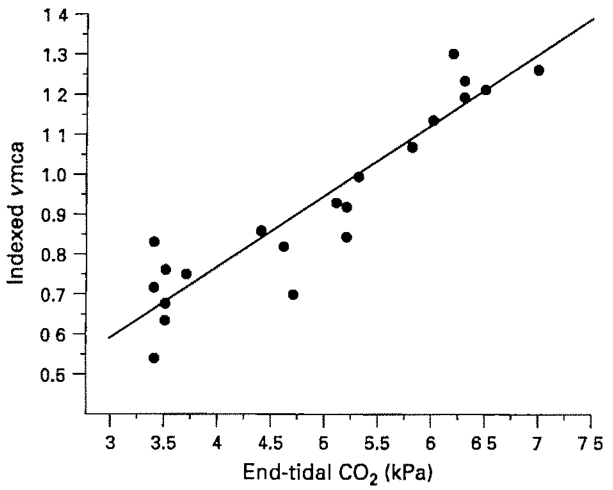

*Figure 6* Indexed flow velocity as a function of end-tidal carbon dioxide concentrations. Regression equations were obtained for data from each individual subject and *v*mca at normocapnia ($FE'_{CO_2}$=5.3 kPa) calculated. All values of CBV were indexed to this value. The resulting regression line ($r^2$=0.86; $P<0.0001$) implies an 18% change in normocapnic *v*mca values for each kPa change in $FE'_{CO_2}$.

## Discussion

Near infrared spectroscopy can provide information on changes in cerebral haemoglobin concentrations and might be expected to be a useful technique to study changes in CBV. Although CBV (and hence cerebral haemoglobin concentrations) would be expected to vary with changes in $Pa_{CO_2}$, we were unable to demonstrate significant changes in Hbt during normoxia at different levels of $Pa_{CO_2}$. However, calculated CBV reactivities from the slopes of Hbdiff/$Sp_{O_2}$ and $HbO_2$/$Sp_{O_2}$ were 1.25 and 1.06 ml 100 $g^{-1}$ $kPa^{-1}$, respectively, and calculated CBV at normocapnia for these two methods were 5.38 and 4.03 ml 100 $g^{-1}$. The discrepancy between CBV reactivity observed with these two methods and the absence of significant change in Hbt concentrations with $FE'_{CO_2}$ changes requires explanation.

It may be that the Hbdiff/$Sp_{O_2}$ and $HbO_2$/$Sp_{O_2}$ slope techniques are more robust methods of measuring CBV than direct measurement of Hbt. Brun and Griesen[8] used NIRS to measure CBF and CBV in neonates and found marked discrepancies between the two methods. CBV reactivity to changes in carbon dioxide was 0.89 ml 100 $g^{-1}$ $kPa^{-1}$ with the Hbdiff/$Sp_{O_2}$ slope method and 0.22 ml 100 $g^{-1}$ $kPa^{-1}$ with the Hbt technique. They attributed this to inaccuracies in the algorithms used to calculate CBV in each case, but suggested that the Hbt technique was less reliable. Their results for carbon dioxide reactivity of CBV using the slope method were similar to ours, but substantially different from other reports. Wyatt and colleagues[7] used changes in Hbt to estimate changes in CBV in response to alterations in $Pa_{CO_2}$ and reported a reactivity of 0.51 ml 100 $g^{-1}$ $kPa^{-1}$ (0.07 ml 100 $g^{-1}$ mm $Hg^{-1}$) in full-term neonates. Grubb and colleagues[11] used positron emission tomography and reported reactivities of 0.04 ml 100 $g^{-1}$ mm $Hg^{-1}$ (0.3 ml 100 $g^{-1}$ $kPa^{-1}$) and a CBV value of 3.6 ml 100 $g^{-1}$ at a $Pa_{CO_2}$ of 5.3 kPa in baboons. Elwell and co-workers[9] used the Hbdiff/$Sp_{O_2}$ slope technique and reported a CBV value of 2.85 ml 100 $g^{-1}$ in healthy adult volunteers. We were unable to find other measurements of changes in CBV with carbon dioxide concentrations in adults.

We observed a difference in the $HbO_2$/$Sp_{O_2}$ slope at different levels of $Pa_{CO_2}$ and the explanation suggested from the work of Elwell and colleagues[9] is that this represents a change in CBV. However, it is important to explore other causes for this phenomenon. One possible mechanism could be that the oxyhaemoglobin dissociation curve is shifted to the left as a result of respiratory alkalosis produced by hyperventilation, thereby decreasing the oxygen availability to tissues.[12] If this were an important effect, the rate at which oxygen was unloaded from haemoglobin in tissues with increasing arterial desaturation might be decreased during hypocapnia, thus contributing to a reduction in the gradient of the $HbO_2$/$Sp_{O_2}$ slope. The issue of whether or not hypocapnic changes in the haemoglobin–oxygen ($Hb–O_2$) dissociation curve contribute to tissue hypoxia remains unresolved. Cruz, Gennarelli and Hoffstad studied 37 brain injured patients with jugular venous monitoring during hyperventilation.[13] They concluded that the Bohr effect was irrelevant to cerebral oxygen availability during hypocapnia unless hypocapnia was profound (arterial pH>7.6). However, no direct information on the effect of $Pa_{CO_2}$ concentrations on the $Hb–O_2$ dissociation curve (e.g. $P_{50}$) was provided and this study primarily addressed the adequacy of oxygen delivery to the brain in "optimally ventilated" patients with head injury and abnormal cerebrovascular reactivity; any conclusions drawn from these data may not necessarily apply to hyperventilation in normal subjects with intact autoregulation. In our experiments, CBF appeared to increase during mild desaturation at hypocapnia in volunteers, suggesting that the threshold for hypoxic vasodilatation may have been breached, despite the literature suggesting a much lower $Sp_{O_2}$ value for initiation of this phenomenon.

The suggestion that hypocapnic vasoconstriction may cause cerebral hypoxia adequate to result in vasodilatation is supported by the findings of Alexander and co-workers[14] who showed a small increase in glucose metabolism and elevated lactate production during hypocapnia in lightly anaesthetized subjects. This implies that excessive hyperventilation may cause a critically reduced tissue $Po_2$ in that there is a shift from aerobic to anaerobic metabolism of glucose. Under such conditions, maintenance of tissue oxygen delivery can be achieved only by reversal of at least part of the hypocapnic vasoconstriction with resulting increases in CBF and CBV. This explanation is supported by the results of a separate study that we performed under the same experimental conditions[15] where we demonstrated significant decreases in estimated cerebrovascular resistance ($CVR_E$) and significant increases in *v*mca during graded arterial desaturation at $Sp_{O_2}$ values of 90%.

This discussion may provide a possible explanation for the discrepancies that we observed between our two measures of CBV reactivity. Conventionally, we would not expect to see alterations in CBF in response to reductions in oxygen saturation that we produced, as other studies[16–18] suggest a $Pa_{O_2}$ threshold for hypoxic vasodilatation of approximately 6.7 kPa. This translates to an arterial oxygen saturation of approximately 85%. However, the increases in *v*mca observed with mild arterial desaturation during hypocapnia suggests that hypoxic vasodilatation was present in our subjects. Under these conditions CBF and CBV would be increased and the requirements for calculating CBV from the Hbdiff/$Sp_{O_2}$ slope might no longer be satisfied.

In summary, our data suggest that if estimation of CBV is made using the Hbdiff/$Sp_{O_2}$ slope method then such measurements would be best made with $Sp_{O_2}$ swings between 93 and 100%. With modification of procedures to account for hypoxic cerebral vasodilatation, the non-invasive methods that we used deserve further investigation as non-invasive monitors of CBF and CBV in *individual* patients who have compromised cerebrovascular autoregulation or abnormal oxygen delivery–demand relationships, or both.

# Use of modified fluid gelatin and hydroxyethyl starch for colloidal volume replacement in major orthopaedic surgery

R. BEYER, U. HARMENING, O. RITTMEYER, S. ZIELMANN, F. MIELCK, S. KAZMAIER AND D. KETTLER

## Summary

We have compared 6% hydroxyethyl starch (HES 200/0.5) with 3% modified fluid gelatin (MFG) for volume replacement in major orthopaedic surgery and studied the effects on haemodynamic state, colloid osmotic pressure, blood clotting and plasma homeostasis. Using a controlled, randomized, single-blind clinical design, we studied 46 consecutive patients undergoing major elective orthopaedic hip surgery. The two groups were comparable in age, body weight and duration of surgery. Patients were maintained haemodynamically stable using both HES and MFG over the entire study. Fluid balance and colloidal replacement volumes were comparable in both groups (median perioperative infusion volume: HES 2500 ml, MFG 2400 ml). Laboratory variables were not clinically different. We conclude that both colloidal solutions were comparable in volume efficacy and effects on plasma oncotic pressure, clotting and plasma homeostasis. In the small number of patients studied, 6% HES 200/0.5 was found to be safe when administered in amounts corresponding to the currently accepted maximum daily dose in Germany and France of 33 ml/kg body weight and 2.0 g/kg body weight, respectively. (*Br. J. Anaesth.* 1997; **78**: 44–50)

**Key words**
Surgery, orthopaedic. Fluid balance. Fluids, i.v.

Synthetic colloids are used widely for replacement of blood loss during major surgical procedures. Defined blood components are transfused only when blood or plasma losses exceed the various limits set for replacement of blood components. The main reason for using colloidal volume replacements is to maintain the circulating blood volume by stabilizing plasma oncotic pressure in the perioperative period. At present, plasma substitutes based on dextran, gelatin and hydroxyethyl starch (HES) are available. The use of these colloids varies greatly between countries in Europe: while dextrans are preferred in Scandinavia, gelatin is the most frequently used synthetic volume replacement solution in the rest of Europe. Only in Germany has HES been the dominant colloid for more than 10 yr. Gelatin solutions are generally regarded as less efficient than HES preparations, although comparative clinical studies are rare.

The aim of this prospective, randomized study was to test if comparable haemodynamic stabilization could be achieved during major orthopaedic procedures using 3% modified fluid gelatin (MFG; mean molecular weight 30 000; Gelafundin) and 6% hydroxyethyl starch (HES 200/0.5, mean molecular weight 200 000, molar substitution 0.5; Hemohes) in the perioperative period, and to determine what quantities of colloid must be infused using a standardized therapeutic plan. In addition, we examined the effects on fluid balance, transfusion of blood products, blood clotting, plasma oncotic function, renal function and other laboratory variables.

## Patients and methods

After approval by the Ethics Committee, and having obtained informed consent, we recruited 48 patients between August 1992 and June 1994 in a randomized, single-blind clinical study. Forty-one of these patients were evaluable (withdrawal of consent ($n$=3) and blood loss too low because of limitation of the planned procedure ($n$=2)). It was not possible to conduct the study double-blind because of the different colours of the two solutions. In addition, gelatin produces foam on shaking and can therefore be distinguished easily from HES.

All patients required major orthopaedic hip surgery with an expected blood loss of >1000 ml. Exclusion criteria were haemoglobin concentration $\leq$11 g dl$^{-1}$, heart failure and coronary artery disease, previous myocardial infarction within the past 6 months, hypertension (>180 mm Hg systolic), impaired renal function (serum creatinine >130 μg litre$^{-1}$), pregnancy, known hypersensitivity to HES or gelatin, use of drugs that may specifically affect blood viscosity or diuresis and clotting disorders (as measured by thrombin time, Quick value and platelet count).

Correspondence to R. B.

We measured arterial pressure, heart rate, central venous pressure, packed cell volume (PCV), haemoglobin, platelet count, prothrombin time (Quick value), thrombin time, partial thromboplastin time, fibrinogen, serum concentrations of electrolytes ($Na^+$, $K^+$, total calcium, $Cl^-$), creatinine, urea, blood glucose, α-amylase, total protein, colloid osmotic pressure (COP) using an Osmostat 050 colloid osmometer (Gonotec; membrane exclusion size 20 000 Da, reference cell 0.9% NaCl) and plasma viscosity using a capillary viscosimeter.

Fluid input and output were monitored during and after surgery. Intraoperative blood loss was calculated from the estimated blood loss in compresses and towels and aspirated volumes (cell saver). The blood volume in drainage was measured after operation. Urine volume was measured using an indwelling catheter in the urinary bladder.

Arterial pressure, heart rate and central venous pressure were monitored continuously during surgery. Postoperative measurements were performed at 3, 6, 12 and 24 h after surgery. Laboratory variables were determined before induction of anaesthesia, every 2 h during surgery, at the end of operation, and 6, 12 and 24 h after operation. At the end of operation and after 6, 12 and 24 h, blood loss was determined and the input and output balance calculated. Urine volume was measured hourly during operation and 3, 6, 12 and 24 h after operation.

All patients were treated by the same anaesthetist (induction with etomidate or barbiturate, fentanyl and pancuronium; maintenance with continuous infusion of fentanyl and midazolam). A mixture of 66% nitrous oxide in oxygen was used with controlled ventilation of the lungs via a tracheal tube. Unfractionated heparin 5000 u. s.c. three times a day was given for postoperative thrombosis prophylaxis.

Fluid and volume replacement and transfusion of blood products were carried out using normal clinical criteria, standardized as follows: preoperative fluid deficit (20 ml $kg^{-1}$) was replaced by 50% in the first hour and by 25% after 2 h and 3 h by infusion of Ringer's acetate solution. Basal fluid replacement (3 ml $kg^{-1}$ $h^{-1}$) was also carried out using Ringer's acetate. Colloidal volume replacement was tailored according to intra- and postoperative haemodynamic variables (central venous pressure, heart rate, arterial pressure and systolic pressure variation), estimated blood loss and clinical status, using only gelatin or HES in the two groups. During operation, haemoglobin concentration was measured photometrically at 15-min intervals using a haemoxymeter (OSM 3, Radiometer). Results were available within 5 min. If haemoglobin concentration decreased to less than 8 g $dl^{-1}$ during surgery, packed red cells were transfused. After surgery haemoglobin concentration was maintained at 10 g $dl^{-1}$. If serum total protein concentration decreased to less than 4 g $dl^{-1}$, human albumin was transfused. If blood loss exceeded 1 litre, blood clotting variables were also analysed at regular intervals. Transfusion of clotting factors in the form of fresh frozen plasma (FFP) was not coupled with preset limits of coagulation factors because clinical experience failed to demonstrate a conclusive relation between global coagulation variables and a clinical bleeding tendency. Therefore, coagulation factors were transfused depending on clinical signs. FFP was administered if diffuse bleeding occurred. This plan was chosen because coupling transfusion of blood components to volume replacement using a rigid mathematical model (e.g. the Berner blood component scheme) was not appropriate for individual patients and had been shown to be impracticable in a pilot study.

All data are expressed as mean (SD). Because of the skewed and non-continuos distribution of fluid balance data, median and lower and upper quartiles were calculated. Between-group comparisons were made using the Mann–Whitney *U* test. The level of significance was $\alpha=0.05$. In order to show equivalence of colloid input, 90% confidence intervals were chosen in accordance with the α used. For presentation of fluid input and output data, box-and-whisker plots were used. The box contains 50% of the data (25–75% percentiles) and is crossed with a bar at the median. Vertical lines are drawn from each end of the box to the corresponding extreme. Mean values are indicated by a diamond.

## Results

There were no differences between groups in patient data. The types of surgical procedures were similar in the two groups (tables 1 and 2). The majority of patients underwent an exchange of a cemented total endoprosthesis (TEP).

Haemodynamic variables (systolic (SAP) and diastolic (DAP) arterial pressures, heart rate (HR) and central venous pressure (CVP)) were similar at the start of the study in both groups and there were no between-group differences during or after surgery. Patients in both groups remained haemodynamically stable (table 3).

PCV and haemoglobin concentrations (Hb) were initially low in both groups (table 4). With the chosen regimen for replacement of blood losses, PCV and Hb decreased during surgery in both groups to approximately 25% and 8.5 g $dl^{-1}$, respectively, and remained at these levels until the end of operation. After operation they stabilized at a slightly higher level (30% and 10 g $dl^{-1}$).

Serum concentrations of sodium and potassium varied slightly and remained within the reference ranges throughout the study. During surgery there was a significantly more pronounced reduction in total calcium concentration in the HES group compared with the gelatin group (table 4). Values in the HES group remained significantly lower up to 12 h after operation.

The Quick value decreased in both groups at the end of operation to approximately 60% and PTT was prolonged (57 s). By 6 h after surgery both variables had returned to normal (table 5). Platelet count decreased in both groups proportionally to blood loss and colloid volume transfused at the end of the operation, to approximately 50% of baseline, and remained at this level after operation. None of the other variables showed any clinically relevant changes or differences between groups.

Creatinine and urea concentrations, and urine excretion were similar in both groups. Blood glucose concentrations increased continuously in both groups, reaching a maximum 6–12 h after operation (approximately 9 mmol litre$^{-1}$) with a trend towards normalization by 24 h after operation. α-Amylase concentrations increased after operation in the HES group to 2.5–3 times baseline values and differed significantly at all times (6, 12, 24 h after operation) from those in the gelatin group.

Total protein (TP) concentration changed to a similar extent in both groups and decreased during operation within 2 h to approximately 60% of baseline and then diminished only slightly until the end of

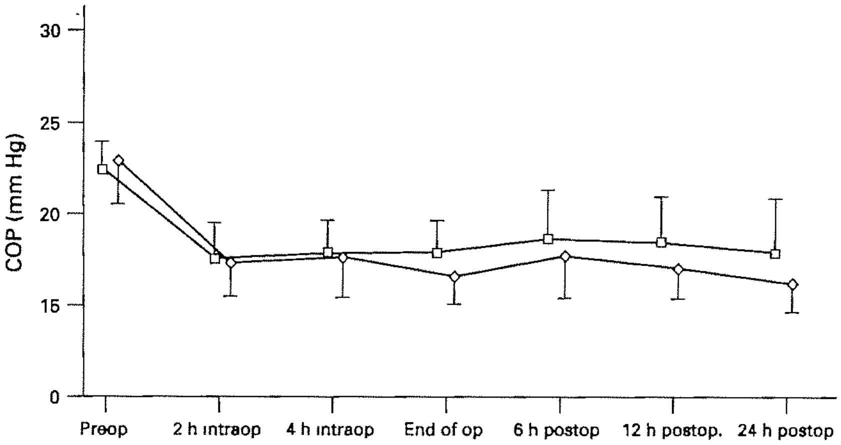

*Figure 1* Colloid osmotic pressure (COP) in the hydroxyethyl starch (□) and modified fluid gelatin (◇) groups (mean, SD), before operation (Preop.), 2 and 4 h during operation (intraop.), at the end of operation and 6 h, 12 h and 24 h after operation (postop.)

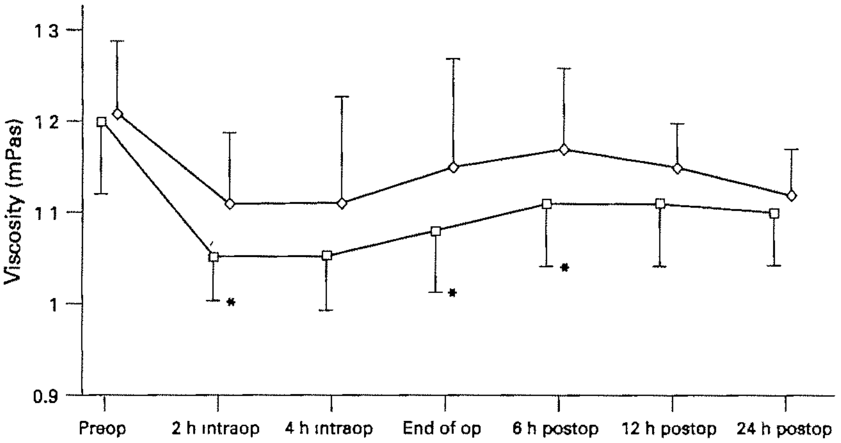

*Figure 2* Plasma viscosity in the hydroxyethyl starch (□) and modified fluid gelatin (◇) groups (mean, SD), before operation (Preop.), 2 and 4 h during operation (intraop.), at the end of operation and 6 h, 12 h and 24 h after operation (postop.) $^*P<0.05$ (group comparison).

operation (table 5). After operation, values stabilized in both groups at about the lower limit of the reference range (5 g $\text{dl}^{-1}$). However, TP values were significantly higher in the gelatin group than in the HES group at the end of operation and 6 h after operation. Plasma oncotic pressure (COP) decreased in both groups within 2 h to approximately 75% of baseline and stabilized at this level after operation with infusion of colloids (fig. 1). There were no significant differences in this variable between the groups. Plasma viscosity (PV) decreased during surgery in both groups in parallel with increasing dilution; the reduction was more marked in the HES group (fig. 2). There were significant between-group differences at 2 h after the start of surgery, at the end of operation and 6 h after operation.

Fluid input and output balances were similar in both groups. Statistical analysis confirmed that both products were equivalent with respect to the amount of colloid infused during operation; median and 90% confidence intervals of the median were the same in both groups (1900–2500 ml and 1500–2500 ml, $\alpha=0.05$). Median postoperative colloid infusion was 500 ml in both groups whereas the upper limit of the 90% confidence interval in the gelatin group was higher than in the HES group (1000 ml and 500 ml) indicating slightly higher postoperative volume requirements in the gelatin group (fig. 3).

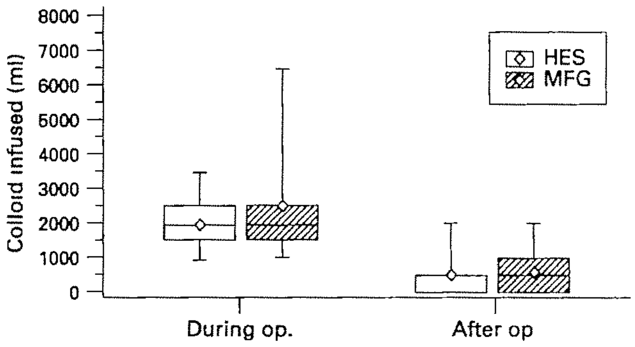

*Figure 3* Amount of colloid infused during operation and the first 24 h after operation in the hydroxyethyl starch (HES) and modified fluid gelatin (MFG) groups. The box contains 50% of the data (25–75% percentiles) and is crossed with a bar at the median Vertical lines are drawn from each end of the box to the corresponding extreme. Mean values are indicated by the diamond.

Total median volume of colloids infused during operation and during the first 24 h after operation was 2500 ml in the HES and 2400 ml in the MFG group; 90% confidence intervals were 1500–2500 ml in the HES group and 2000–3000 ml in the MFG

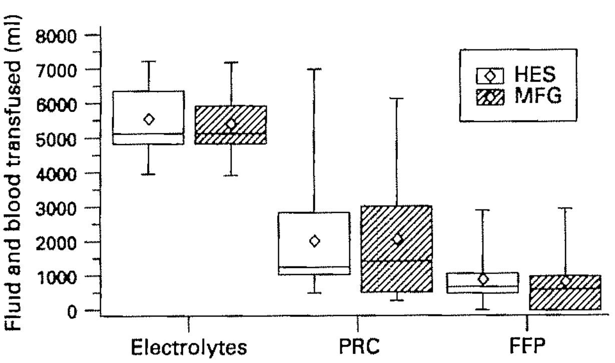

*Figure 4* Amount of perioperative electrolyte input and blood components transfused (packed red cells (PRC) and fresh frozen plasma (FFP))in the hydroxyethyl starch (HES) and modified fluid gelatin (MFG) groups. The box contains 50% of the data (25–75% percentiles) and is crossed with a bar at the median. Vertical lines are drawn from each end of the box to the corresponding extreme. Mean values are indicated by the diamond.

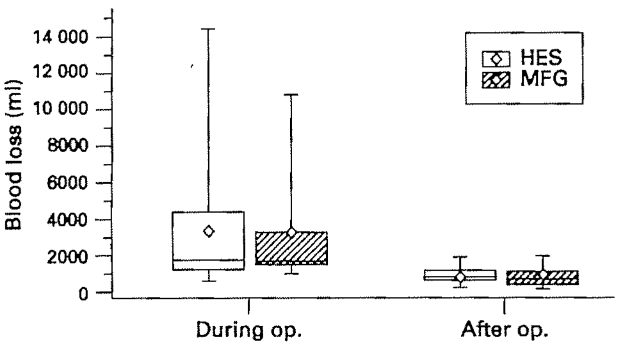

*Figure 5* Intra and postoperative blood losses in the hydroxyethyl starch (HES) and modified fluid gelatin (MFG) groups. The box contains 50% of the data (25–75% percentiles) and is crossed with a bar at the median. Vertical lines are drawn from each end of the box to the corresponding extreme. Mean values are indicated by the diamond.

group. However, there were no significant differences between groups, as indicated by the *U* test ($P$=0.52). Additional analysis of a subgroup of 10 patients in each group, whose operations lasted longer than 4 h, showed a trend towards increased colloid requirements in the gelatin group during operation (median volume infused 2.5 *vs* 1.9 litre; ns).

There was no difference in electrolyte infusion and use of blood products (packed red cells, fresh frozen plasma) (fig. 4).

Urine excretion was comparable in both groups during and after operation (median volume: HES 250 ml and 3620 ml *vs* MFG 290 ml and 3265 ml). The same was true for blood losses during and after operation (HES 1800 ml and 840 ml *vs* MFG 1750 ml and 775 ml) (fig. 5).

There were no allergic reactions to the infused substances in any patient.

## Discussion

Patients were recruited into this study only if they were undergoing major hip surgery. This condition was fulfilled as shown by the mean duration of operation of 4 h and the median perioperative blood loss of 2.6 litre in both groups.

Regarding the criteria for evaluation of the efficiency of colloidal volume replacement solutions, various pharmacological and clinical terms have been used as synonyms, including volume effect, volume efficacy, duration of action, duration of volume effect, (elimination) half-life and intravascular retention time. The most reliable variable for comparison purposes is the plasma elimination half-life or concentration half-life ($T_{1/2}$) defined as the time required for the concentration of a colloid in blood to decrease to 50% of its initial peak value. However, various factors affect this value, such as the rate of infusion, method of infusion (hypervolaemic or normovolaemic infusion), concentration of solution used and choice of observation period, and these have led to marked differences in published values. Thus various values for the intravascular half-life of similar HES solutions (HES 200/0.5; HES 264/0.45) have been reported in the scientific literature, ranging from 2.7 to 22 h.[1 2] The aim of this study was therefore to compare the clinical effects (haemodynamic stabilization, infusion volume required) of two standard colloids in major orthopaedic procedures under clinical conditions and using standardized infusion regimens.

Infusion of two volume replacement solutions was tailored to haemodynamic variables, estimated blood loss and clinical status. Invasive monitoring with a Swan–Ganz catheter was not indicated in these patients because of the associated risks. The same anaesthetist undertook all operations and a high degree of standardization of volume replacement was achieved.

There were no significant differences between groups with regard to circulation variables either before induction of anaesthesia or during or after operation. Haemodynamic variables showed that stabilization of the circulatory system was achieved over the entire study using infusion of both 3% MFG and 6% HES 200/0.5. Similar volumes of gelatin and HES were required during and after operation, while both the initial volume effect and plasma elimination half-life of HES are generally thought to be higher than those of MFG. At the same time, there were no noteworthy differences in the use of electrolytes and blood products or in blood loss and urine output. Only in patients with a duration of surgery of 4 h or more with correspondingly greater median blood loss (>2.6 litre) was a slight increase in requirements (~25%, corresponding to 500 ml) apparent in the gelatin group, but this could not be confirmed statistically. Thus both volume replacements fulfilled the criteria for efficient medium-term volume replacement.

There are few previous comparative studies of the efficacy of gelatin and HES. Beards and colleagues[3] found a comparable increase in pulmonary capillary wedge pressure, cardiac output and arterial oxygen transport in intensive care patients within 30 min after infusion of 500 ml of 4% MFG and high molecular weight starch (6% HES 450/0.7). They concluded from their study that the initial effects of succinylated gelatin and HES on haemodynamics and oxygen transport did not differ. Furic and colleagues[4] chose a pragmatic method in their prospective study of 987 patients. They could not confirm that 3.5% dextran 40 was more efficient than 3% MFG, as presumed on the basis of their pharmacological data. The same volumes of both colloids were used during the study. The aim of the study by Bérard and colleagues[5] was to determine if the theoretical advantages of HES compared with MFG in terms of duration of action operate in clinical practice and lead to a reduction in the volume required to maintain normovolaemia in critically ill patients. Although a slightly smaller number of HES units was infused, this was not significantly different from the number of units of MFG infused per patient (4.29 *vs* 5.02 u.). However, a highly significant difference was seen in the mean cost of volume replacement per patient. The use of HES multiplied the cost per patient by 1.72.

PCV decreased in both groups during operation to approximately 25%, while values of 30% were maintained after operation. These low PCV and haemoglobin values were well tolerated in all cases.

In contrast with gelatins, all HES solutions have a recommended upper dose limit because of their effects on coagulation factors, platelets and fibrinoformation. The dose limit was defined in the past on the basis of the volume infused, irrespective of the concentration of the solution. Recently, German and French licensing authorities have accepted that the upper dose limit of starches with a molar substitution of 0.5 should be defined by the amount of active substance administered. Thus in those countries it is now possible to infuse 20 ml/kg body weight per day of the 10% and 33 ml/kg body weight per day of the 6% solution, corresponding to HES 2 g/kg body weight per day.

The global clotting variables, which were additionally affected by perioperative administration of heparin, did not differ between the two groups. No patient showed dramatically altered values or clinically relevant bleeding tendency, and blood loss and transfusion volumes were comparable. This is not unexpected for gelatin as it is generally accepted that gelatin solutions do not have any specific effect on clotting, apart from the dilutional effect.[6] In contrast, highly substituted HES preparations (HES 200/0.62; 450/0.7) affect factor VIII complex to a greater extent than can be explained by dilution.[7] Bleeding complications have been reported, predominantly after infusion of large quantities or in association with repeated administration, especially in neurosurgical patients.[8–12] The results of this study in which a mean of 27 ml $kg^{-1}$ was infused over the intraoperative and 24-h postoperative period, with 10 patients receiving 6% HES 200/0.5$\geq$30 ml $kg^{-1}$ and seven patients $\geq$40 ml $kg^{-1}$, are in agreement with other investigations, in which various mean molecular weight HES preparations with a molar substitution of up to 0.5 apparently affected clotting to a much lesser degree.[13–16]

Apart from α-amylase, serum chemistry variables did not differ significantly between groups. The increase in α-amylase activity after infusion of HES is a well recognized phenomenon and is caused by formation of an enzyme–substrate complex between α-amylase and HES, with delayed elimination because of its size.[17] The increase in amylase does not signify pathology, but would be important in the differential diagnosis of suspected pancreatic disease. The stress response and related hormonal changes caused hyperglycaemia in both groups after operation, with no significant differences between them.

Apart from serum total calcium, electrolyte concentrations remained in the normal range. The decrease in total calcium in both groups can be explained by the known "rule of thumb" whereby a decrease in albumin concentration of 1 g $dl^{-1}$ is accompanied by a decrease in serum total calcium of 0.8 mg $dl^{-1}$.[18] The significantly higher values in the gelatin group compared with the HES group are probably because gelatin, in contrast with HES, contains calcium 1.4 mmol $litre^{-1}$, approximately the same as physiologically ionized calcium. Studies by Vogt, Schönberger and Kilian[19] have confirmed that HES does not specifically affect ionized calcium, even at higher doses.

Total protein (TP) and colloid osmotic pressure (COP) were similar in both groups. The significantly higher TP concentrations in the MFG group at the end of operation can be explained by the fact that gelatin is a polypeptide and participates in the biuret reaction for total protein determination.

COP values were similar throughout the observation period. The initial decrease in COP in both groups from approximately 22 to 17 mm Hg within the first 2 h after the start of operation was caused by infusion of approximately 20 ml $kg^{-1}$ of electrolyte solution for fluid replacement and consequent dilution. Values in both groups were then stable at this level for up to 24 h after operation.

Plasma viscosity decreased significantly compared with baseline values in both groups, solely because of the increasing haemodilution during the course of the operation. Presumably because of its additional specific effect on blood rheology, values in the HES group were significantly lower at 2 h after the start of operation, at the end of operation and 6 h after operation.

In summary, despite their different pharmacological properties, similar amounts of both solutions were required to achieve haemodynamic stabilization in patients throughout the course of the study. Fluid balance was similar in both groups. Only with operations lasting more than 4 h and median blood losses of more than 2.6 litre did the shorter plasma elimination half-life of gelatin solution cause increased requirements of about 25%, although this difference could not be confirmed statistically. HES 200/0.5 (6%) does not, therefore, have a significantly greater volume effect than 3% MFG in the procedures investigated here. There were no noteworthy differences in the effects on plasma oncotic pressure, blood clotting or plasma homeostasis. Restricted to the small number of patients, 6% HES 200/0.5 was found to be safe when administered in amounts corresponding to the currently accepted maximum daily dose in Germany and France of 33 ml/kg body weight, and 2.0 g/kg body weight, respectively.

# Cardiorespiratory changes during gynaecological laparoscopy by abdominal wall elevation: comparison with carbon dioxide pneumoperitoneum

A. CASATI, G. VALENTINI, S. FERRARI, R. SENATORE, A. ZANGRILLO AND G. TORRI

## Summary

We have studied the cardiorespiratory changes produced by abdominal wall elevation (AWE) or carbon dioxide pneumoperitoneum (PN) in 20 women undergoing gynaecological laparoscopy. Arterial pressure, heart rate, lung/chest compliance and blood-gas tensions were measured 10 min after induction of general anaesthesia (T0), 10 min after abdominal distension in the supine position (T1) and 10 min after the Trendelenburg position was assumed (T2). Visual analogue scores for pain were recorded 1 and 6 h after the end of surgery. We found that lung/chest compliance was reduced significantly in group PN at T1 and T2 compared with both T0 and group AWE. Diastolic arterial pressure increased significantly in group PN at T1 and T2 compared with both T0 and group AWE, while it remained unchanged in group AWE. Arterial $P\text{CO}_2$ increased significantly only in group PN after pneumoperitoneum, while oxygenation was almost unchanged in both groups. AWE patients had greater abdominal pain 1 h after surgery. Six hours after surgery pain was similar in the two groups. These data indicate that abdominal wall elevation reduced pulmonary compliance less than a pneumoperitoneum in patients undergoing gynaecological laparoscopy. (*Br. J. Anaesth.* 1997; **78**: 51–54)

**Key words**
Surgery, laparoscopy. Carbon dioxide, pneumoperitoneum. Cardiorespiratory system, effects.

Laparoscopic abdominal surgery has been used increasingly in the past years for gynaecological surgery, cholecystectomy and more complex and difficult surgical procedures (e.g. vagotomy, herniorrhaphies, antireflux procedures, splenectomy, bowel resection).

The limited skin incision with laparoscopic procedures is usually associated with less postoperative pain and faster recovery.[1 2] Carbon dioxide pneumoperitoneum is the common method used to obtain abdominal distension for laparoscopy. Some complications such as hypercapnia and acidosis,[3] gas embolism,[4] pneumothorax, subcutaneous emphysema[5] and deep venous thrombosis[6] have been reported after carbon dioxide pneumoperitoneum. These complications may adversely affect patient outcome, especially in those with cardiac or respiratory disease.[7]

Alternatives to carbon dioxide pneumoperitoneum, helium and nitrous oxide pneumoperitoneum, have been studied: these gases avoid the increase in $Pa_{\text{CO}_2}$ and acidosis but do not resolve problems related to the increase in intra-abdominal pressure.[8 9]

Many methods of abdominal wall elevation have been developed for laparoscopy.[10 12] The Hanon technique allows for elevation of the abdominal wall ventrally, using an inflatable balloon or a fan retractor inserted into the peritoneal cavity through the base of the umbilicus. The balloon is connected to an automated mechanical lifting arm attached to the operating table. This system is designed to provide 13.6 kg or less of lift to the anterior abdominal wall, which approximates to the pressure provided by 1.95 kPa (15 mmHg) of pneumoperitoneum.[10] Abdominal wall elevation should theoretically reduce the negative effects on the diaphragm and abdominal great vessels caused by pneumoperitoneum.

The aim of this study was to compare the effects of carbon dioxide pneumoperitoneum with abdominal wall lift using a mechanical retractor device in patients undergoing gynaecological pelvic surgery.

## Patients and methods

With the approval of the local Ethics Committee and informed consent, we studied 20 women, ASA I, undergoing gynaecological laparoscopy for ovarian surgery.

Premedication comprised diazepam 5 mg orally and atropine 0.5 mg i.m., 30 min before induction of anaesthesia. After a 18-gauge i.v. cannula was inserted into the forearm, anaesthesia was induced with fentanyl 0.001 mg $\text{kg}^{-1}$ i.v. and thiopentone 5 mg $\text{kg}^{-1}$ i.v. Vecuronium 0.1 mg $\text{kg}^{-1}$ i.v. was given to facilitate tracheal intubation with a cuffed tube.

Anaesthesia was maintained with 1–1.5% end-tidal isoflurane in an oxygen-enriched air mixture ($FI_{O_2}$=0.5) to maintain arterial pressure and heart rate within acceptable ranges. Intermittent positive pressure ventilation (IPPV) was applied using a Drager–Cato volume cycled ventilator, with an inspiratory flow rate of 25 litre min$^{-1}$, ventilatory frequency 12 bpm, tidal volume 10 ml kg$^{-1}$ and an inspiratory:expiratory ratio of 1:2. Ventilatory variables were not changed during the study.

Intraoperative monitoring included continuous ECG (lead II), non-invasive arterial pressure using an automated cuff, pulse oximetry, inspired oxygen fraction, end-tidal carbon dioxide concentration, end-tidal isoflurane concentration, airway pressure and minute ventilation.

Static compliance of the whole respiratory system (lung/chest wall compliance ($CPL_{RES}$)) was calculated by dividing expired tidal volume by static pressure (plateau pressure) after a 1-s inspiratory pause. To evaluate $\dot{V}/\dot{Q}$ mismatching, we calculated the ratio of arterial oxygen to inspired oxygen partial pressure ($Pa_{O_2}/FI_{O_2}$) as an index of pulmonary shunt,[13] and arterial to end-tidal carbon dioxide gradient, as an index of dead space.[14]

Patients were allocated randomly to receive abdominal distension by standard carbon dioxide pneumoperitoneum (group PN) or by the abdominal wall elevation device (group AWE). Carbon dioxide pneumoperitoneum was created using a Veress needle inserted into a small intra-umbilical incision. An electronic variable-flow insufflator terminated flow when an intra-abdominal pressure of 1.6 kPa (12 mm Hg) was reached. A 10-mm trocar was inserted in place of the needle to provide and maintain insufflation adequate for surgery. A video laparoscope was then inserted through the same trocar and the operative field was seen. In group AWE, an inflatable ring-shaped retractor was introduced into the peritoneal cavity (mesogastrium) via a small incision at the base of the umbilicus, using the Hanon technique, and then inflated.[10] The retractor was attached to an automated mechanical arm and the abdominal wall was elevated using 13.6 kg of tension to provide adequate vision of the operating field. The laparoscope was then inserted into the peritoneal cavity via the umbilical incision and through the hole present in the inflatable retractor to see the pelvic and abdominal organs. Positive pressure insufflated gases were not necessary for surgery.

Patients were then placed in a 30° Trendelenburg position. Heart rate (HR), systolic (SAP) and diastolic (DAP) arterial pressures, and static lung/chest compliance ($CPL_{RES}$) were recorded 10 min after induction of general anaesthesia before abdominal insufflation or wall elevation (T0), 10 min after abdominal distension or carbon dioxide insufflation (T1) and 10 min after Trendelenburg positioning (T2). At the same time, arterial blood was obtained for measurement of blood-gas tensions (IL BGM 1312; Instrumentation Laboratory, Lexington, MA, USA). All measurements were made before surgery was started.

At 1 and 6 h after the end of surgery, the intensity of abdominal pain was recorded using a visual analogue score (VAS 10 cm).

Data were collected and analysed using a statistical software package (StatView II SE, Abacus Concepts Inc., Berkeley, CA, USA). Analysis of variance for repeated measures with Sheeffé and Dunnet's tests of multiple comparison, Mann–Whitney test and chi-square test were used to asses changes over time both within and between groups. $P<0.05$ was considered significant. Data are reported as mean (SD) or median (range) for ordinal data.

## Results

Patient data are shown in table 1. Patients with preoperative hypotension or cardiopulmonary disease were excluded from the study. There were no

perioperative complications caused by anaesthesia or surgery.

Mean baseline HR was similar in both groups and did not change significantly during the study ($P$=0.26) (fig. 1). In group PN, DAP increased significantly after abdominal insufflation and after Trendelenburg positioning compared with both before insufflation (T0) and group AWE ($P$=0.04 and 0.02, respectively). SAP did not change significantly in either group during the study ($P$=0.11).

In the pneumoperitoneum group, lung/chest compliance decreased significantly after (T1) compared with before insufflation (T0) ($P$=0.01) and with group AWE ($P$=0.0001); there was a further reduction in $CPL_{RES}$ when the Trendelenburg position was assumed (T2) compared with both T0 ($P$=0.01) and group AWE ($P$=0.0006) (fig. 1). In AWE patients, lung/chest compliance did not change after abdominal elevation (T1) compared with values after induction (T0) ($P$=0.25), but it was significantly reduced after Trendelenburg positioning compared with T0 values ($P$=0.005). Compliance was significantly higher in group AWE compared with group PN both at T1 and T2 ($P$=0.0001 and 0.0006, respectively).

There were no significant changes in pH after abdominal distension and positioning (table 2). $Pa_{O_2}/FI_{O_2}$ and arterial to end-tidal carbon dioxide gradient did not change significantly after insufflation or abdominal lift or after Trendelenburg positioning in both groups (table 2). In contrast, $Pa_{CO_2}$ increased significantly in group PN after pneumoperitoneum ($P$=0.02) with a mean difference compared with group AWE of approximately 0.665 kPa (5 mm Hg), 10 min after Trendelenburg positioning (table 2).

One hour after the end of surgery, patients treated with the abdominal wall retraction procedure had greater abdominal pain than group PN ($P$=0.03). None of the patients received postoperative analgesic drugs and the nociceptive stimulus was short-acting; 6 h after surgery there were no significant differences in abdominal pain between the two groups (table 3).

## Discussion

The two different techniques used for laparoscopy produce a difference in diaphragm displacement and consequently lead to different degrees of reduction in functional residual capacity (FRC) in the two groups of patients during anaesthesia. Respiratory system compliance was reduced significantly using the pneumoperitoneum technique. Changes in respiratory compliance in this study were in agreement with previously reported data.[15] Another significant reduction in respiratory system compliance was caused by Trendelenburg positioning.[16]

In the AWE group, airway pressure and respiratory system compliance were almost unaffected by abdominal wall distension. When Trendelenburg position was used, respiratory system compliance was lower than values measured after induction of anaesthesia; values of $CPL_{RES}$, however, were significantly higher at this time in the AWE compared with the PN group.

Despite the relevant effects on lung/chest compliance, in this study we did not observe a significant difference in gas exchange in the two groups. In group PN, only $Pa_{CO_2}$ increased progressively because of its rapid absorption into the circulation via the peritoneum. Our data were obtained 10 min after abdominal distension and then 10 min after Trendelenburg positioning. This time interval might have been insufficient to produce effects on pulmonary gas exchange; consequently, the decrease in FRC, produced by reduction in compliance, could be expected to worse oxygenation in group PN after a prolonged observation time.

Carbon dioxide load, with its direct and indirect haemodynamic effects,[17] together with known increased cardiac afterload produced by intra-abdominal pressure elevation,[18] might be the determinant of the increase in diastolic arterial pressure in group PN. These modifications may lead to an increase in myocardial work and myocardial oxygen consumption.

It is known that carbon dioxide pneumoperitoneum produces an increase in central venous pressure by forcing blood from the abdominal organs into the central venous reservoir[19,20] and a high preload reduces coronary flow by decreasing coronary artery perfusion caused by increased ventricular wall stress.[21]

The abdominal wall elevation method, avoiding the increase in intra-abdominal pressure, might produce less effects on afterload and preload than pneumoperitoneum laparoscopy, further reducing the risks associated with laparoscopic procedures, especially in patients with poor cardiovascular reserve.

One hour after the end of surgery, group AWE had greater abdominal pain than the pneumoperitoneum group. This difference was probably a result of the smaller area of abdominal wall on which traction is applied in AWE compared with PN patients: in carbon dioxide pneumoperitoneum, abdominal distension involves all of the abdominal wall. Moreover, visual analogue scores were similar in the two groups 6 h after surgery. We believe that, unless statistically significant, the difference found 1 h after surgery is not clinicaly relevant in the postoperative management of patients.

Our data indicated that during gynaecological laparoscopy, abdominal wall elevation did not affect the respiratory system and gas exchange, reduced the negative effects on the cardiorespiratory system produced by pneumoperitoneum and may have improved the risk/benefit ratio of laparoscopic techniques.

Our patients were all young, relatively healthy females, undergoing short duration surgical procedures: they tolerated well pneumoperitoneum and the Trendelenburg position. The physiological effects of prolonged carbon dioxide insufflation into the peritoneum, combined with variations in patient positioning, have a major impact on cardiorespiratory function in elderly patients, with pre-existing cardiac or respiratory disease, undergoing surgical procedures with a longer duration than gynaecological laparoscopy. Further studies are required in these different groups of patients. Nevertheless, we believe that this technique of abdominal wall lifting and gasless laparoscopy should be advocated. The potential benefits of abdominal wall retraction may be useful for patients undergoing laparoscopic upper abdominal procedures of longer duration, in the reverse Trendelenburg position, and particularly when the patients are elderly with co-existing cardiac or respiratory disease, or both.

LABORATORY INVESTIGATIONS

# Isoflurane increases the uptake of glutamate in synaptosomes from rat cerebral cortex

M. LARSEN, E. HEGSTAD, J. BERG-JOHNSEN AND I. A. LANGMOEN

## Summary

We have studied the effect of increasing concentrations of isoflurane on high- and low-affinity uptake of L-glutamate using synaptosomes from rat cerebral cortex. In the high-affinity uptake range, 0.5% isoflurane had no effect on uptake velocity, while 1.5% and 3.0% isoflurane caused an increase in mean *V*max to 131 (SEM 54) and 210 (103) % of control, respectively. There was no significant change in the $K_m$ value. *V*max and $K_m$ values for low-affinity uptake of L-glutamate were unchanged by 1.5% isoflurane. These results provide evidence for an isoflurane-induced increase in high-affinity uptake of glutamate into presynaptic terminals. This effect may contribute to a reduction of transmitter in the synaptic cleft and thereby decreased excitatory synaptic transmission. (*Br. J. Anaesth.* 1997; **78**: 55–59)

**Key words**
Anaesthetics volatile, isoflurane. Nerve, transmission Nerve, neurotransmitters. Nerve, synaptosome. Rat.

As early as 1906, Sherrington reported that chloroform blocks reflex activity in the spinal cord at lower concentrations than those needed to inhibit impulse propagation along nerve fibres.[1] Later studies have shown that other inhalation agents depress excitatory synaptic transmission in the superior cervical ganglion[2] and in various parts of the central nervous system, including the spinal cord,[3] cuneate nucleus,[4] olfactory bulb,[5] olfactory cortex[6 7] and dentate area.[8]

Isoflurane, a halogenated methyl-ethyl-ether, is used widely because of its advantages compared with older volatile anaesthetics. In the rat hippocampus, isoflurane inhibits excitatory signal transduction by depression of the activity in thin unmyelinated, afferent fibres,[9] reduction of excitatory synaptic transmission[10 11] and hyperpolarization of the postsynaptic neurone.[12 13]

The effect on excitatory synaptic transmission seems quantitatively to be the most important.[10 14] Synaptic transmission may be depressed by drug-induced reduction in the release of the transmitter from the presynaptic terminal, altered reuptake or reduced sensitivity of the postsynaptic receptor. Intracellular recordings from lumbosacral motor neurones in cats have shown that diethyl ether[15] depresses synaptic potentials, thus decreasing the amount of excitatory transmitter released while leaving the chemosensitivity of the postsynaptic membrane unchanged. We have shown recently that isoflurane reduced both synaptic (calcium-dependent) and non-synaptic (calcium-independent) potassium-stimulated release of glutamate from rat cerebral cortex,[16] without affecting the response on the postsynaptic membrane.[11] The effect on the presynaptic terminal may be caused by alteration in the uptake mechanism in addition to reduction in the release of transmitter.

To study further how isoflurane acts presynaptically, we have investigated the effect on neuronal reuptake mechanisms of glutamate using synaptosomes prepared from rat cerebral cortex.

## Materials and methods

### PREPARATION OF SYNAPTOSOMES

Synaptosomes were prepared, as described by McMahon and colleagues.[17] Briefly, Wistar rats, treated according to approved rules, were killed and the brain carefully removed. The cortex from each hemisphere was isolated and homogenized in 15 ml of sucrose 0.32 mol $litre^{-1}$ (1–4 °C) using a glass homogenizer with a Teflon pestle (clearance=0.25 mm). The homogenate was centrifuged at 3000×*g* for 3 min and the supernatant spun at 15 000 × *g* for 30 min. The pellet formed consisted of two layers. The superficial layer containing the majority of the synaptosomes[17] was resuspended selectively in 6 ml of sucrose 0.32 mol $litre^{-1}$, stored at 1–4 °C and used within 6 h from preparation. The pellet was diluted before use in HEPES-buffered medium (HBM) containing (mmol $litre^{-1}$): NaCl 117.5, KCl 3.75, $MgCl_2$ 1, $CaCl_2$ 1.3, $KH_2PO_4$ 1.25, $NaHCO_3$ 20, glucose 10, HEPES 20, NaOH 6 (pH 7.4). Fresh HBM was prepared daily.

### L-GLUTAMATE UPTAKE

Synaptosomes (2–4 mg protein ml$^{-1}$) were incubated at 37 °C in a series of different concentrations of L-glutamate corresponding to the high- ($5.5\times10^{-6}$ to $2.5\times10^{-5}$ mol litre$^{-1}$) and low- ($1\times10^{-4}$ to $1\times10^{-3}$ mol litre$^{-1}$) affinity uptake systems, respectively.[18] A fixed concentration ($2.2\times10^{-9}$ mol litre$^{-1}$) of radiolabelled glutamate (46 Ci mmol$^{-1}$) (Amersham Laboratories, Buckinghamshire, UK) was added to each L-glutamate concentration. The chambers, each containing 1.5 ml of incubation medium, were sealed and saturated with 95% oxygen–5% carbon dioxide. Isoflurane 0.5, 1.5 or 3.0% (Abbot Laboratories Ltd., Kent, UK) was added using a vaporizer (Fortec, Ohmeda 5250 RGM, Englewood, USA) and the medium shaken gently every 30 s. Uptake was terminated at 4 min as the synaptosomes were placed on a Millipore filter (0.65 mm), washed in 5 ml of 0.9% NaCl (1–4 °C) and dissolved in 1 ml of 10% Triton X-100 (t-octylphenoxypolyethoxyethanol) (Sigma Chemical Co., St Louis, MO, USA) for 10 min. The suspension was then removed from the filter before scintillation fluid (Pico-Fluor 15, Packard, Groningen, The Netherlands) was added. The labelling was measured by counting disintegrations per minute in a β-scintillation counter (LKB Wallac, San Fransisco, CA, USA) with a counting efficiency of 25–30%. Protein content was measured using the method of Lowry and colleagues.[19]

In each setting, a control experiment and experiments using 0.5, 1.5 and 3.0% isoflurane were performed using one batch of synaptosomes from one brain. The number of experiments ($n=9$) thus reflects the number of rats used.

Results are presented as mean (SEM). Differences between the two groups were tested using the Wilcoxon signed rank sum test and for three or more groups with the Kruskal–Wallis test. Differences were considered significant when $P<0.05$.

## Results

In the first set of experiments, concentrations of L-glutamate were increased from $0.55\times10^{-5}$ to $2.5\times10^{-5}$ mol litre$^{-1}$ corresponding to the high-affinity uptake system with a reported $K_m$ value of $0.2\text{–}5.0\times10^{-5}$ mol litre$^{-1}$.[18,20] Uptake velocity for L-glutamate was measured in the control situation and under the influence of isoflurane in increasing concentrations (0.5, 1.5 and 3.0 %). The results are summarized in table 1. By plotting the mean values from table 1 in a double reciprocal plot (Lineweaver–Burk plot) as shown in figure 1, straight lines with regression coefficients ($r^2$) of 0.905 to 0.992 were drawn. *V*max and $K_m$ were calculated from the intercepts of the lines on the *Y* and *X* axis, respectively. The lowest concentration, 0.5% isoflurane, had no effect on uptake velocity as the control and 0.5% isoflurane plots were parallel. However, 1.5 and 3.0% isoflurane produced an increase in uptake velocity, as seen from the reduced steepness of the plot in figure 1. As all lines cross the *X* axis at approximately the same point, the high-affinity transporter to glutamate was presumably unaffected by isoflurane.

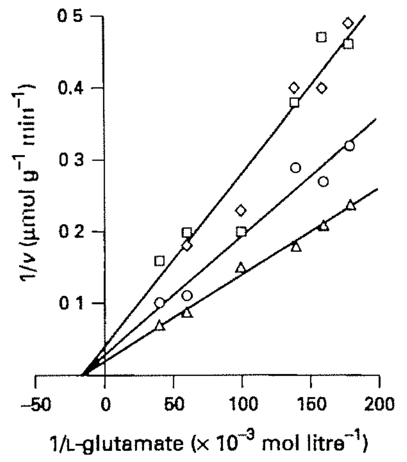

*Figure 1* Double-reciprocal plots of the effect of 0.5, 1.5 and 3.0% isoflurane on high- affinity glutamate transport in cortical synaptosomes. Regression lines are drawn. (Control (□), $r^2=0.905$; 0.5 % isoflurane (◇), $r^2=0.952$; 1.5% isoflurane (○), $r^2=0.958$; and 3.0% isoflurane (△), $r^2=0.992$.) Each point represents the mean of nine experiments. For variability, see table 2.

Calculated $K_m$ and *V*max values for the high-affinity uptake system are presented in table 2. *V*max in the control situation was 1.47 (1.25) μmol g$^{-1}$ min$^{-1}$, and there was no significant change in response to 0.5% isoflurane. However, 1.5 and 3.0% isoflurane increased *V*max to 1.97 (0.80) and 3.09 (1.52) μmol g$^{-1}$ min$^{-1}$, respectively ($P<0.05$), corresponding to 131% and 210% increases, on average. $K_m$ for the high-affinity transporter was 52.9 (50.2) μmol litre$^{-1}$. Isoflurane 0.5, 1.5 and 3.0% had no effect on $K_m$.

In the second set of experiments the effect of isoflurane on the low-affinity uptake system was investigated, using glutamate concentrations from $1\times10^{-4}$ to $1\times10^{-3}$ mol litre$^{-1}$. The double reciprocal plot in

| Isoflurane 3.0% | 61.7 (30.4) | 3.09 (1.52)* |

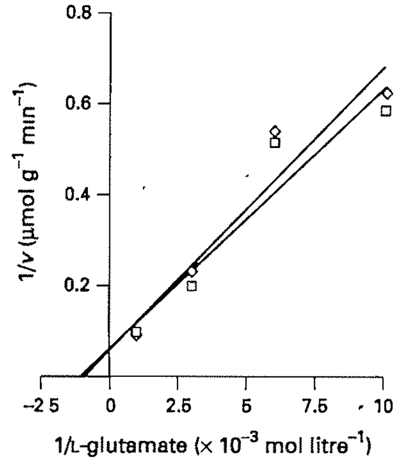

*Figure 2* Double-reciprocal plot of the effect of 1.5% isoflurane on the low-affinity uptake system for L-glutamate in synaptosomes. Regression lines are drawn. (Control (□, $r^2=0.909$; 1.5 % isoflurane (◇), $r^2=0.911$.) Each point represents the mean of seven experiments.

figure 2 describes a straight line with a regression coefficient of 0.904. As 0.5% isoflurane had no effect on the high-affinity uptake system, 1.5% isoflurane, which corresponds to approximately 1 MAC (minimal alveolar concentration), was tested. As is evident from figure 2, showing almost identical plots during control and isoflurane administration, 1.5% isoflurane had no effect on uptake velocity. *V*max for the low-affinity uptake system was calculated as 16.3 (11.9) µmol g$^{-1}$ min$^{-1}$, and 1.5% isoflurane had no effect on *V*max. The calculated $K_m$ value for the low-affinity uptake system was 1.0 (0.9) mmol litre$^{-1}$. $K_m$ was unaffected by 1.5% isoflurane.

## Discussion

Volatile anaesthetics seem to exert their effects in the central nervous system by affecting several different sites, including both excitatory and inhibitory pathways; for example isoflurane affects conduction in unmyelinated fibres, excitatory synaptic transmission, membrane properties of the postsynaptic neurone and inhibitory synaptic transmission.[9,11,12,21] However, the quantitatively most important effect is probably decreased excitatory synaptic transmission[10] which can be caused by decreased amount of transmitter released from the presynaptic terminal, more efficient reuptake from the synaptic cleft or reduced sensitivity of the postsynaptic membrane. This study showed an anaesthetic-induced increase in the uptake velocity of transmitter glutamate presynaptically. Taken together with the previously demonstrated decrease in transmitter release,[16] increased uptake further attenuates the excitatory synaptic transmission by faster termination of transmitter action.

The synaptosomal preparation used in this study is a mixture of pinched off nerve endings and to a large extent free from glial cells and cell debris.[22] The preparation consists of sealed plasma membrane vesicles with preserved release and uptake mechanisms.[23] Synaptosomes from rat cerebral cortex exhibit both high- and low-affinity uptake mechanisms for glutamate[18] and a high-affinity uptake system for γ-aminobutyric acid.[23] Because of well functioning secretory and uptake mechanisms, the method is regarded as well suited for studying neuronal release and uptake mechanisms of transmitters.[20]

Both neurones and glial cells have uptake systems important in terminating the effect of transmitter glutamate in the synaptic cleft.[20] We have demonstrated uptake systems both in low- and high-affinity areas with $K_m$ values of approximately 1 mmol litre$^{-1}$ and 50 µmol litre$^{-1}$, respectively. These are in agreement with previous reports of two different uptake systems in rat cortical synaptosomes, one in the low-affinity area with a $K_m$ value of approximately 1 mmol litre$^{-1}$ and the other in the high-affinity area with a $K_m$ value of 2–50 µmol litre$^{-1}$.[18,24] The physiological role of the low-affinity transporter is still unclear although it has been suggested that it prevents peak concentrations of extracellular glutamate.[25] The high-affinity uptake system, which is active in glial cells and in glutamatergic neurones, is important in terminating transmitter action.[25]

The mechanisms that regulate these transporter proteins are not fully understood. Four different glutamate transporters have recently been identified and cloned in human brain.[25,26] EAAT 1 (excitatory amino acid transporter) is localized only in the plasma membrane of glial cells, EAAT 2 in neurones and glial cells, EAAT 3 in neuronal plasma membranes[27] and EAAT 4 predominantly in cerebellum.[26] EAAT 1 is activated as protein kinase C (PKC) catalyses phosphorylation of the transporter protein.[28] In cultures of glial cells, stimulation of PKC activity with phorbol esters increases the high-affinity transport of L-glutamate seen as increased *V*max whereas $K_m$ is unaltered.[29] PKC stimulation also enhanced *V*max, but not $K_m$, of a cloned γ-aminobutyric acid transporter in *Xenopus* oocytes through translocation of the transporter from a cytoplasmic compartment to the plasma membrane.[30] Several volatile anaesthetics, including halothane and to some extent isoflurane, increase PKC-mediated phosphorylation of several rat brain cytoplasmic proteins in a calcium- and phospholipid-dependent manner.[31] One of these proteins, a major substrate for PKC, might have a regulatory role in neurotransmission.[31] As halothane and enflurane appear to inhibit PKC itself,[32] potential targets for anaesthetic action in intact neurones could be complex processes leading to release of intracellular calcium or production of diacylglycerol, which are both required for PKC activation. Furthermore, experimental observations have indicated that neurones may release factors that influence the activity of glutamate and GABA transporters in glial cells and thus suggest an alternative mechanism of action for anaesthetic agents.[33]

The potency of inhaled anaesthetics is described as the minimum alveolar concentration (MAC) of the gas producing surgical anaesthesia in 50% of subjects. The MAC value for isoflurane in middle-aged humans is 1.15% and for rats, 1.38%, and does not alter with increasing duration of anaesthesia. Concentrations exceeding 1 MAC are needed to depress the electroencephalogram (EEG) and at 2 MAC the EEG becomes isoelectric.[34] In this study, isoflurane was added to the incubation chambers in clinically relevant doses. The chambers were sealed in order to minimize gas leakage. If a small leakage should occur, however, the effect of the anaesthetic would occur at lower concentrations and the effect would thus be underestimated.

Isoflurane (0.5, 1.5 and 3.0%) increased high-affinity uptake of glutamate. A possible explanation could be an anaesthetic-induced increase in PKC activity catalysing phosphorylation and thereby activation of the transporter protein. This is in agreement with the previously mentioned activation of EAAT 1 in glial cells by PKC,[28 29 35] causing increased uptake velocity. Furthermore, this is in agreement with studies where halothane, and to some extent isoflurane, enhanced PKC activity on brain cytoplasmic proteins.[31] According to these observations, halothane and isoflurane can upregulate glutamate uptake through PKC-mediated activation of the transporter protein located on the presynaptic plasma membrane or induce translocation of transporters from the cytosol to the plasma membrane. This would subsequently reduce the amount of transmitter available for the postsynaptic membrane and restrict the time the transmitter is available in the synaptic cleft.

In this study, we have demonstrated that 1.5 and 3.0% isoflurane increased the uptake velocity in a dose-dependent manner. Isoflurane thus reduced excitatory synaptic transmission by reducing the amount of transmitter in the synaptic cleft.

## Acknowledgements

This study was supported by the Norwegian Council for Heart Diseases. Professor Ansgar O. Aasen and professor Helge Nornes provided excellent working conditions. We thank Elisabeth Try Valø and Cecilie Sandberg for technical assistance.

# Sevoflurane modulates both $GABA_A$ and $GABA_B$ receptors in area CA1 of rat hippocampus

K. Hirota and S. H. Roth

## Summary

It has been suggested that volatile anaesthetics enhance synaptic inhibition via γ-aminobutyric acid (GABA) in the central nervous system. We have examined the effects of sevoflurane on $GABA_A$ and $GABA_B$ receptors in rat hippocampus *in vitro.* Extracellular recordings were used to record field potentials in rat CA1 pyramidal neurones of transverse hippocampal slices, stimulated electrically via stratum radiatum input. Sevoflurane 0.4–5.0 vol% decreased the amplitudes of population spikes (PS) of CA1 neurones in a concentration-dependent (calculated $ED_{50}=6.31$ vol%) and reversible manner. The $GABA_A$ antagonist, bicuculline methiodide $5\times10^{-5}$ mol litre$^{-1}$, induced oscillations (multiple spikes) and blocked the inhibitory actions of sevoflurane in the initial component (up to 24.8 ms) of the oscillation. The latter portion of the oscillation (greater than 24.8 ms) was depressed by sevoflurane. The $GABA_B$ antagonist, phaclofen $5\times10^{-4}$ mol litre$^{-1}$ partially blocked the effects of sevoflurane on the latter portion of the bicuculline-induced oscillation. Sevoflurane 2.0 vol% significantly enhanced paired-pulse (PS2/PS1) facilitation (from 128.4% to 155.5% at an inter-stimulus interval of 37.9 ms); this enhancement was blocked by phaclofen. Stimulus–response relationships revealed that 2.0 vol% sevoflurane increased the intensity of threshold for PS generation to 109.8% of control. Both the $GABA_A$ agonist, muscimol $2\times10^{-5}$ mol litre$^{-1}$ and the $GABA_B$ agonist, (±)-baclofen $10^{-5}$ mol litre$^{-1}$, potentiated the effects of sevoflurane. Sevoflurane enhanced thresholds by 137.1% and 138.5% of control in the presence of muscimol and (±)-baclofen, respectively. The results demonstrate that sevoflurane at clinical concentrations activated both $GABA_A$- and $GABA_B$-mediated inhibitions in area CA1 of the hippocampus, and that sevoflurane and GABA agonists (muscimol and baclofen) acted on different domains on the $GABA_A$ and $GABA_B$ receptors, respectively. (*Br. J. Anaesth.* 1997; **78**: 60–65)

**Key words**
Anaesthetics volatile, sevoflurane. Brain, hippocampus. Receptors, amino acid. Rat.

Although the mechanism(s) by which volatile anaesthetics decrease neuronal excitability in the central nervous system are unknown, recent studies revealed that reduction in intrinsic excitability or synaptic response, or both, underlies the actions of general anaesthetics.[1–4]. Nicoll[5] suggested that general anaesthetics produce inhibitory actions because of γ-aminobutyric acid (GABA)-mediated synaptic inhibition.[6] The GABA analogue, THIP (4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol) was found to induce anaesthesia when administered systemically to rats.[7] Recent investigations have distinguished at least two types of GABA receptors: the bicuculline-sensitive receptor, termed $GABA_A$, which is a ligand-gated $Cl^-$ channel,[8] and the $K^+$ channel-modulating receptor, $GABA_B$, which is a G protein-coupled receptor.[9] It has been shown that halothane, enflurane and isoflurane modulate $GABA_A$ receptor-mediated $Cl^-$ currents.[10–14] Although possible involvement of $GABA_B$ receptors in the inhibitory actions of anaesthetics was suggested,[15 16] little is known of the effects of anaesthetics on $GABA_B$ receptors. Sevoflurane (fluoromethyl 2,2,2-trifluoro-1-[trifluoromethyl] ethyl ether) is a relatively new anaesthetic with rapid induction and recovery properties. It is reported that sevoflurane induces $Cl^-$ currents in CA1 neurones in rat hippocampus.[17] The main objectives of this study were to determine the involvement of $GABA_A$ and $GABA_B$ receptors in the actions of sevoflurane in area CA1 of rat hippocampus.

Previous studies have defined the selective agonist for the $GABA_A$ receptor, muscimol, the agonist for the $GABA_B$ receptor, baclofen, and the selective antagonist for the $GABA_A$ receptor, bicuculline.[8 9] Phaclofen, the phosphonic acid derivative of baclofen, was shown recently to be a selective $GABA_B$ antagonist.[18] These GABAergic agents are

useful in determining the physiological significance and interactions of GABA receptors. In order to examine the modulation of hippocampal $GABA_A$ and $GABA_B$ receptors by sevoflurane, we have studied the effects of sevoflurane on the electrophysiological and pharmacological properties of the stratum radiatum input to CA1 pyramidal neurones of rat hippocampus *in vitro*. Extracellular recordings were used for the pharmacological investigations of synaptic activities.

## Materials and methods

### SOLUTIONS AND DRUGS

Artificial cerebrospinal fluid (ACSF) was made with 18 MΩ purity water (Baunstead Nanopure) and Analar grade chemicals. The composition was (mmol litre$^{-1}$): NaCl 124, KCl 5, $CaCl_2$ 2, $NaH_2PO_4$ 1.25, $MgSO_4$ 2, $NaHCO_3$ 26, glucose 10. ACSF (pH 7.3±0.1) was pre-cooled (8–10 °C) and saturated with a 95% oxygen–5% carbon dioxide gas mixture before use (pH 7.3–7.4).

Most of the chemicals used were obtained from BDH Inc. (Ontario, Canada) with the exception of muscimol, bicuculline methiodide (Sigma Chemical Co., MO, USA), (±)-baclofen and phaclofen (Research Biochemicals Inc., MA, USA). Sevoflurane was generously donated by Maruishi Pharmaceutical (Osaka, Japan).

### PREPARATION

The technique for preparation of rat hippocampal slices was identical to the method described previously by MacIver and Roth.[19] After obtaining approval from the Animal Care Committee of the University of Calgary, male Sprague–Dawley rats, weighing 100–200 g, were anaesthetized with ether and the brain removed rapidly and placed in pre-cooled (8–10 °C) ACSF. Transverse slices (350 μm) of hippocampus were cut using a tissue chopper (Stoelting, IL, USA). Slices were placed on a nylon mesh screen at the gas–liquid interface in a recording chamber. The temperature of the recording chamber was controlled at 35 °C with a pre-warmed (35 °C), perfusing (1.5 ml min$^{-1}$) ACSF and a pre-warmed and humidified 95% oxygen–5% carbon dioxide gas mixture (1.5 litre min$^{-1}$). Slices were incubated for 90 min without electrical stimulation.

### ELECTROPHYSIOLOGICAL TECHNIQUE

Bipolar nichrome stimulating electrodes were placed on the stratum radiatum to activate excitatory synaptic inputs to CA1 pyramidal neurones. A glass microelectrode was placed in the cell body regions of CA1 neurones for recording extracellular field potentials. The resistance of the microelectrode was 3–5 MΩ when filled with NaCl 2 mol litre$^{-1}$.

Stimuli were square-wave pulses generated by a Grass (MA, USA) S88 stimulator and a SIU5 stimulus isolation unit. A stimulus pulse of 0.05–0.5 ms duration was delivered at 0.1 Hz. The minimal stimulus intensity that elicited a maximal population spike (PS) amplitude ("maximal stimulus") was used except in experiments for stimulus–response (S-R) analysis. In some experiments, a paired-pulse stimulus was used to examine paired-pulse facilitation. In this case, the inter-stimulus interval was adjusted to elicit a maximal response, and the ratio of the first (PS1) and second population spike (PS2) amplitudes was determined (fig. 1). Field potentials were amplified with a Grass P15 amplifier (low- and high-frequency filters set at 1 Hz and 10 kHz), and digitally stored on VCR using a Neuro Data (NY, USA) DR-384 A/D converter for later analysis.

### DATA ANALYSIS

The amplitudes of PS and excitatory post-synaptic potential (EPSP) measurements were essentially the same as those described previously.[20] The duration of oscillation in the presence of bicuculline methiodide was determined as the distance between the first peak of PS and the last detectable peak. Results were collected in a group of four, averaged and stored as a single record. All preparations used in this study exhibited PS amplitudes of at least 5 mV and control variability less than 5% during the initial data acquisition period and after washout of sevoflurane.

Experiments were conducted on 54 hippocampal slices prepared from 49 rats. Results are expressed as mean (SEM), and comparisons were made using Student's *t* test. A probability of chance occurrence of less than 5% ($P<0.05$) was considered significant. Non-liner functions were fitted to the data using the SigmaPlot program (Jandel, CA, USA)

### DRUG ADMINISTRATION

Sevoflurane was applied as a vapour to the tissue chamber via the pre-warmed and humidified 95% oxygen–5% carbon dioxide gas stream above the slices, using a Tec 3 sevoflurane vaporizer (Ohmeda, West Yorkshire, UK). Concentrations, expressed as volume percentage (vol%), refer to dial settings on the vaporizer. The vaporizer had been calibrated previously with an anaesthetic gas analyser (Capnomac; Datax, Finland). Sevoflurane was applied for a minimum of 5 min to reach equilibrium, as the preliminary experiments demonstrated that the onset times for sevoflurane effects were less than 30 s and that maximum effects reached a plateau within 3 min (not shown) because of low solubility (a saline–gas coefficient of 0.370)[21] of the anaesthetic. Concentrations of sevoflurane in the perfusate of the recording chamber were measured using gas chromatography. The concentrations of anaesthetic in solution were found to be linearly correlated ($0.56 \times 10^{-3}$ mol litre$^{-1}$ per 1%) with the percentage in the gas phase up to 5.0%.

The GABAergic agents (muscimol, bicuculline methiodide, (±)-baclofen, phaclofen) were added to the ACSF at required concentrations just before each experiment. Slices were exposed for 15 min to the drug-containing ACSF, which was found to be sufficient time to produce stable effects.

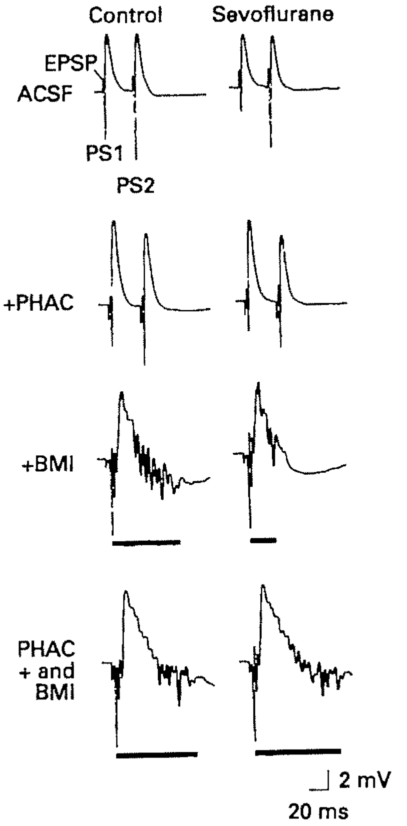

*Figure 1* Effects of 2.0 vol% sevoflurane on field potentials of CA1 neurones under normal artificial cerebrospinal fluid (ACSF) conditions, and after modulation of sevoflurane actions by phaclofen (+PHAC, $5\times10^{-4}$ mol litre$^{-1}$) and/or bicuculline methiodide (+BMI, $5\times10^{-5}$ mol litre$^{-1}$). Population spikes (PS1, PS2) (downward, negative wave) and excitatory postsynaptic potentials (EPSP) (positive, upward wave) were elicited by either paired-pulse stimuli (ACSF, +PHAC) or single stimuli (+BMI, +PHAC and BMI) at a fixed intensity and duration (0.1 Hz). Note that the later part of the oscillatory potentials (indicated by the straight lines in the lower two traces) were depressed by sevoflurane in the presence of bicuculline methiodide, whereas in the presence of both phaclofen and bicuculline methiodide the oscillation remained unchanged after administration of sevoflurane. Data in each series of records were obtained from separate preparations.

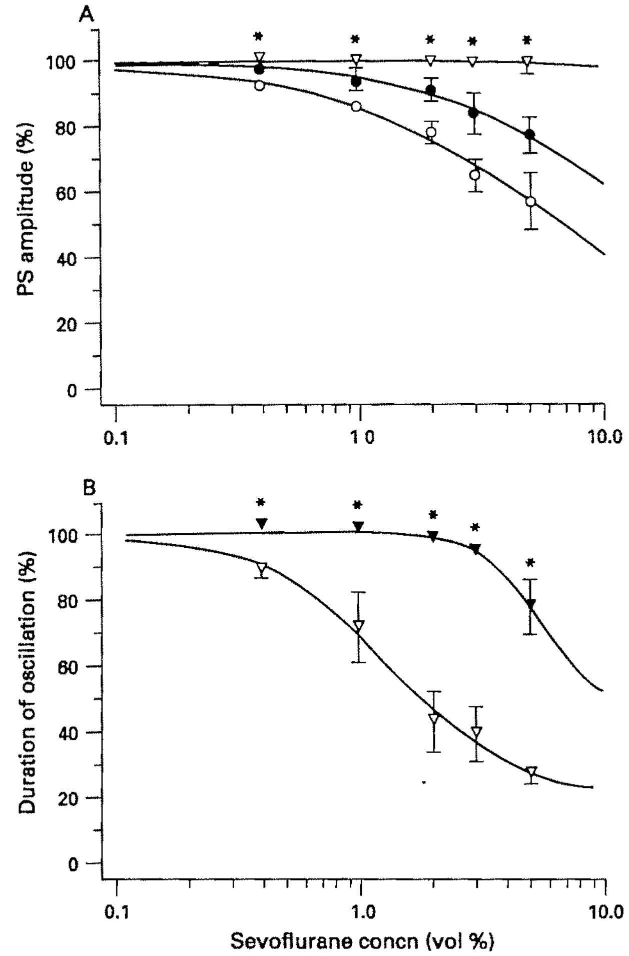

*Figure 2* Concentration–response relations of the amplitude of PS (A) and duration of oscillatory potentials (B) for sevoflurane in the absence (○) and presence of GABA antagonists, phaclofen (PHAC, $5\times10^{-4}$ mol litre$^{-1}$) (●), bicuculline methiodide (BMI, $5\times10^{-5}$ mol litre$^{-1}$) (▽) and PHAC and BMI (▼). Data points are percentage of control (mean, SEM). $^*P<0.05$ compared with data in the absence of GABA antagonists (A) or in the presence of BMI (B).

## Results

Figure 1 shows representative recordings of the effects of 2.0 vol% sevoflurane on field potentials of CA1 pyramidal neurones in the absence (top trace) and presence of GABA antagonists (lower three traces). Field potentials were elicited with either paired-pulse stimuli (upper two traces) or single stimuli (lower two traces) at 0.1 Hz.

Sevoflurane decreased the first (PS1) and second PS (PS2) amplitudes in a concentration-dependent and reversible manner (fig. 1, fig. 2A) without significant change in EPSP amplitudes. Using the SigmaPlot program, the data were fitted to an equation of the form:

$$\text{Amplitude (\%)} = \frac{k^n}{k^n + C^n} \times 100 \qquad (1)$$

where $k$=concentration producing 50% inhibition (ED$_{50}$), $C$=concentration of sevoflurane, and $n$=Hill's coefficient. The $k$ value (calculated ED$_{50}$) and Hill's coefficient obtained from data in figure 2A for sevoflurane were 6.3 vol% and 1.0, respectively.

### GABA ANTAGONISTS AND SEVOFLURANE

The GABA$_B$ antagonist phaclofen $5\times10^{-4}$ mol litre$^{-1}$ alone had no consistent effect on the shape of field potentials (fig. 1). Although phaclofen shifted the concentration–response curve for sevoflurane to the right ($k$=15.0 vol%), this change was not significant (fig. 2A). In contrast, the GABA$_A$ antagonist bicuculline methiodide $5\times10^{-5}$ mol litre$^{-1}$ caused long-lasting oscillatory potentials (92.5 (15.0) ms, $n$=4), and blocked the depressant actions of sevoflurane on the initial amplitude of the oscillatory PS (fig. 1). The amplitudes of PS1 (fig. 1, upper two traces) or the initial PS amplitudes (lower two traces) were used for data analysis.

Sevoflurane depressed the latter portion of bicuculline-induced oscillation (indicated by the straight lines in fig. 1). A concentration of 5.0 vol% decreased the duration of the oscillation to 25.9 (2.8) % of control (24.8 (6.7) ms, $n$=4) in the presence of bicuculline methiodide. However, phaclofen

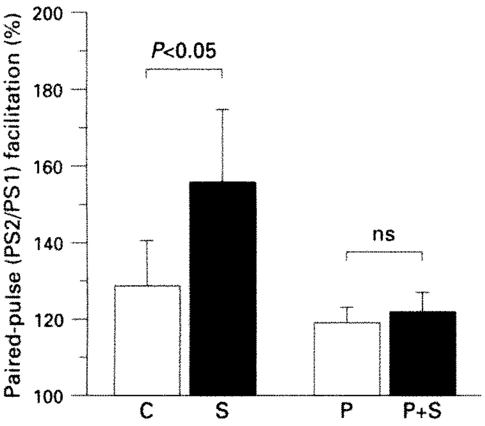

*Figure 3* Effects of sevoflurane and/or phaclofen on paired-pulse (PS2/PS1) facilitation. The inter-stimulus interval that elicits a maximal PS2 amplitude was used to determine the facilitation. Data are expressed as mean (SEM). C=Control (ACSF), $n=7$; S=2.0 vol% sevoflurane, $n=7$; P=phaclofen $5\times10^{-4}$ mol litre$^{-1}$, $n=3$; P+S=phaclofen and sevoflurane, $n=3$. Note that in the absence of phaclofen, sevoflurane significantly ($P<0.05$) enhanced paired-pulse facilitation, while in the presence of phaclofen, sevoflurane had no significant effect.

in combination with bicuculline methiodide partially blocked the decrease in duration induced by sevoflurane (fig. 2B). Data in figure 2B were fitted to a modification of equation (1):

$$\text{Amplitude }(\%)=\left(\frac{k^n(1-R)}{k^n+C^n}+R\right)\times 100 \qquad (2)$$

where $R$=sevoflurane-resistant portion (duration) of the oscillation; $k$ and $R$ values obtained from data in figure 2B were 1.3 vol% and 0.18, respectively, for bicuculline methiodide and 5.3 vol% and 0.44 for phaclofen with bicuculline methiodide.

Figure 3 shows the effects of sevoflurane and phaclofen on paired-pulse facilitation (PS1/PS2). A maximal PS2/PS1 facilitation was 128.4 (12.0) % ($n=7$) at an inter-stimulus interval of 37.9 (2.4) ms in the control state. Sevoflurane 2.0 vol% significantly enhanced the PS2/PS1 ratio to 155.5 (19.3) % ($n=7$). This change was caused mainly by marked depression of PS1, while PS2 was less affected. On the other hand, phaclofen $5\times10^{-4}$ mol litre$^{-1}$ decreased PS2/PS1 to 118.4 (3.9) % ($n=3$) at an inter-stimulus interval of 38.3 (2.0) ms and blocked the enhancement of PS2/PS1 by 2.0 vol% sevoflurane.

### GABA AGONISTS AND SEVOFLURANE

Figure 4 shows examples of the stimulus–response (S-R) relationships of PS in the absence and presence of GABA agonists. Stimulus intensity was varied to determine S-R relationships at a fixed stimulus duration and frequency. The data were fitted with non-linear functions generated with the SigmaPlot program; the maximal amplitudes of PS (*A*max) and thresholds for PS generation were calculated. Sevoflurane 2.0 vol% significantly enhanced the threshold (109.8 (3.8) % of control, $n=5$), however, *A*max remained unchanged (98.6 (1.3) % of control) in the absence of GABA agonists. The GABA agonists muscimol $2\times10^{-5}$ mol litre$^{-1}$ and (±)-baclofen $10^{-5}$ mol litre$^{-1}$ significantly increased the threshold and decreased *A*max.

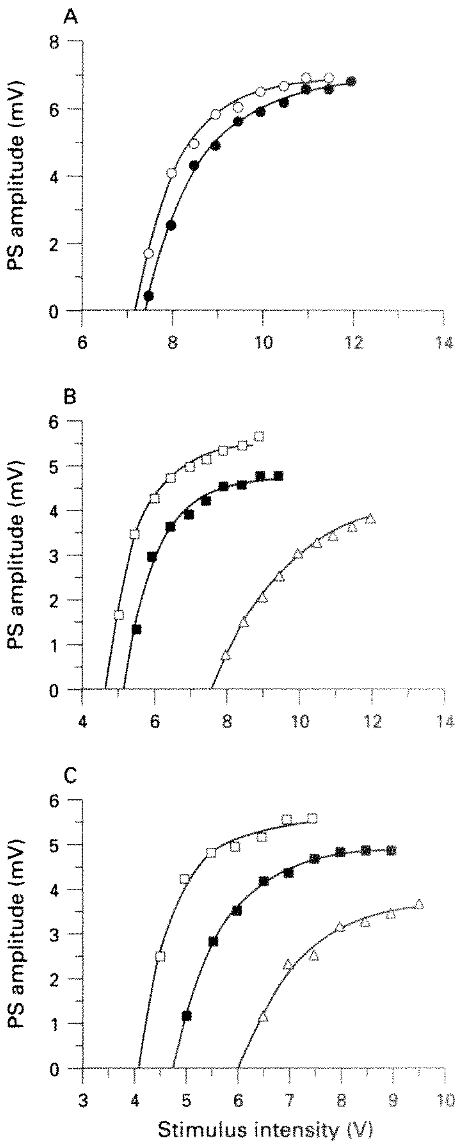

*Figure 4* Representatives of the stimulus–response (S-R) relations of PS amplitude in the presence of GABA agonists and/or 2.0 vol% sevoflurane. A: Effects of sevoflurane (control (○); 2.0 vol% sevoflurane (●)). B: Effects of $GABA_A$ agonist and/or sevoflurane (control (□); muscimol $2\times10^{-5}$ mol litre$^{-1}$ (■); muscimol and sevoflurane (△)). C: $GABA_B$ agonist and/or sevoflurane (control (□); (±)-baclofen ($10^{-5}$ mol litre$^{-1}$ (■)); baclofen and sevoflurane (△)). Data in each series of records were obtained from separate preparations.

Each GABA agonist potentiated the effects of sevoflurane (see fig. 4B, 4C). Sevoflurane 2.0 vol% increased the threshold (137.1 (6.2) % and 138.5 (11.2) %) and decreased *A*max (87.1 (2.8) % and 71.4 (5.9) %) in the presence of muscimol ($n=4$) and baclofen ($n=3$), respectively. These changes were significantly different from those observed in the absence of GABA agonists. Figure 5 shows a summary of the *synergistic* interactions between sevoflurane and the GABA agonists. The combination of 2.0 vol% sevoflurane and baclofen $10^{-5}$ mol litre$^{-1}$ increased the threshold by 56.8%, while the summation of the threshold changes produced by sevoflurane and baclofen independently was 23.5%.

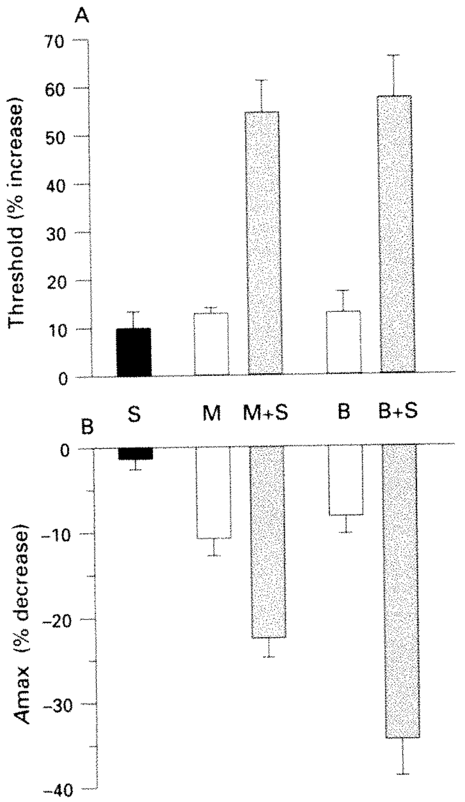

*Figure 5* Summary of the effects of sevoflurane and/or GABA agonists on threshold (A) and *A*max (B). Data (mean, SEM) are expressed as percentage increase (A) or percentage decrease (B) compared with control. S=2.0 vol% sevoflurane, $n=5$; M=muscimol $2\times10^{-5}$ mol litre$^{-1}$, $n=4$; M+S=muscimol and sevoflurane, $n=4$; B=baclofen $2\times10^{-5}$ mol litre$^{-1}$, $n=3$; B+S=baclofen and sevoflurane, $n=3$. All bar charts were significantly different ($P<0.05$) from control except for sevoflurane (2.0 vol%, S) in B.

## Discussion

The rat hippocampal slice preparation has served as a useful model system to study the mechanisms of action of general anaesthetics, and may be one of the major targets for anaesthetic action.[22] In addition, the anatomy, physiology and pharmacology have been well documented in numerous reports.

It had been demonstrated that the actions of sevoflurane on hippocampal PS may be caused by modulation of both GABA$_A$- and GABA$_B$-mediated inhibitions. Postsynaptic GABA$_A$ and GABA$_B$ receptors are thought to generate the fast inhibitory postsynaptic potential (f-IPSP) and the slow inhibitory postsynaptic potential (s-IPSP), respectively, in the central nervous system.[6 23] The f-IPSP and s-IPSP have been reported to have mean latencies of onset of ~3 ms and 29 (SEM 2) ms ($n=9$), respectively, in CA1 neurones of the rat hippocampus.[24] Bicuculline blocked the inhibitory actions of sevoflurane on the initial period of oscillation (figs 1, 2A). The duration of sevoflurane-resistant oscillation was up to 24.8 ms. These results indicate that sevoflurane activates GABA$_A$ responses to enhance f-IPSP.

Although GABA$_A$ antagonists have been reported to block the inhibitory actions of halothane, enflurane and isoflurane in rat hippocampal neurones,[13 25] less attention has been paid to the decrease in duration of bicuculline-induced oscillation by anaesthetics. The observed inhibition in the sevoflurane-sensitive component of the oscillation (>24.8 ms) is most likely a result of postsynaptic GABA$_B$-mediated inhibition, as the combination of phaclofen and bicuculline significantly blocked sevoflurane depression during the duration of the oscillation (figs 1, 2B).

Phaclofen, however, did not completely block the effects of sevoflurane on bicuculline-induced oscillation. Sevoflurane 5.0 vol% reduced the duration to 76.8% of control, and the calculated sevoflurane-sensitive component of the duration was 56% in the presence of phaclofen (fig. 2B). This suggests that other mechanism(s) in addition to GABAergic inhibition may be involved in the actions of sevoflurane. As it is reported that isoflurane inhibits voltage-gated Ca$^{2+}$ currents in rat hippocampal pyramidal neurones,[2] sevoflurane could affect ion channels of pyramidal neurones to reduce cellular excitability in area CA1. On the other hand, the results of effects of volatile anaesthetics on excitatory synaptic transmissions in the CNS have been contradictory. Although conventional extracellular and current-clamp experiments revealed that volatile anaesthetics have no consistent effect on excitatory synaptic transmissions in rat hippocampal CA1,[15 26] patch-clamp studies demonstrated that halothane and isoflurane depressed glutamate receptor-mediated excitatory postsynaptic currents in hippocampal neurones.[14] In our study, sevoflurane had no significant effects on EPSP amplitudes, suggesting that sevoflurane had minimal actions on excitatory synaptic transmissions.

Sevoflurane enhanced paired-pulse (PS2/PS1) facilitation and this enhancement was blocked in the presence of phaclofen (fig. 3). Although the mechanisms for the facilitation are not well understood, presynaptic GABA$_B$ receptors have been suggested to play a major role in the facilitation of CA1 neuronal activity of rat hippocampus. It is suggested that activation of GABA$_B$ autoreceptors after the first stimulation transiently depresses GABA release from presynaptic terminals.[23 27] Thus increased facilitation by sevoflurane may be attributed to activation of presynaptic GABA$_B$-mediated depression of GABA release.

Although volatile anaesthetics were reported to produce GABA$_A$-mediated inhibitions as a result of enhancement of GABA receptor–Cl$^-$ channel complex,[10–14] little is known of the effects of anaesthetics on hippocampal GABA$_B$ receptors. It has been reported that the GABA$_B$ agonist baclofen produces anaesthesia when administered systemically to mice,[16] and that prolongation of paired-pulse depression by halothane, enflurane and isoflurane in rat hippocampus *in vivo* might be caused by modulation of GABA$_B$ receptor-mediated inhibition.[15] Our results demonstrate that sevoflurane may enhance the effectiveness of the postsynaptic GABA$_B$ receptor and presynaptic GABA$_B$ autoreceptor.

If the mechanisms for GABA receptor activation by sevoflurane are the same as those for GABA agonists, the combination of sevoflurane and GABA agonists would be expected to induce additive or less than additive effects. Our results, however, demonstrated that administration of sevoflurane in the presence of muscimol or baclofen evoked a synergistic response (figs 4, 5). Hence different mechanisms for sevoflurane and GABA agonists may be involved in the activation of GABA receptors. Our results are in accordance with the proposed hypothesis that the binding site for general anaesthetic molecules is located in the GABA receptor complex, and that this site is different from the GABA recognition site.[28 29]

In summary, we have shown that sevoflurane activates postsynaptic $GABA_A$ receptors, and post- and presynaptic $GABA_B$ receptors in CA1 pyramidal neurones of rat hippocampus *in vitro*, and that sevoflurane and GABA agonists (muscimol, baclofen) acted on different domains of the GABA receptor complex. $GABA_A$- and $GABA_B$-mediated inhibition may represent an important role for sevoflurane in producing general anaesthetics.

## Acknowledgments

We thank Dr K. Toriizuka for performing assays of sevoflurane bath concentration and Maruishi Pharmaceutical Co. Osaka, Japan for the gift of sevoflurane and a sevoflurane vaporizer. This study was supported by the Medical Research Council of Canada.

# Volatile anaesthetic effects on calcium conductance of planar lipid bilayers formed with synthetic lipids or extracted lipids from sarcoplasmic reticulum

T. ANDOH, T. J. J. BLANCK, I. NIKONOROV AND E. RECIO-PINTO

## Summary

Volatile anaesthetics are known to increase leakage of calcium from the light fraction of skeletal sarcoplasmic reticulum (L-SR) which has no calcium release channels. To explore the role of the lipid environment, we have examined the effect of volatile anaesthetics on calcium conductance ($g_{Ca}$) of lipid membranes. Planar lipid bilayers were formed with a mixture of synthetic phospholipids and cholesterol, resembling the composition of SR membranes, or with lipids extracted from skeletal L-SR. $g_{Ca}$ was estimated by calculating the calcium transference number ($t_{Ca}$) using diffusion potential measurements. Membranes formed with L-SR-extracted lipids had a higher $g_{Ca}$ than membranes formed with synthetic lipids. Volatile anaesthetics increased total conductance and $g_{Ca}$ in a dose-dependent manner, but did not affect $t_{Ca}$ or membrane specific capacitance. In membranes formed with L-SR-extracted lipids, isoflurane induced the largest increase in $g_{Ca}$ (1260 (SEM 304) % increase, $n$=4, 0.94 mmol litre$^{-1}$), followed by enflurane (264 (75) %, $n$=5, 1.88 mmol litre$^{-1}$) and halothane (53 (33) %, $n$=5; 1.54 mmol litre$^{-1}$). In membranes formed with synthetic lipids, volatile anaesthetic-induced increases in $g_{Ca}$ followed the same trend but were larger. Volatile anaesthetics increased $g_{Ca}$ without changing the ionic selectivity of membranes. However, the magnitude of the increase in $g_{Ca}$ in the presence of volatile anaesthetics cannot account for the previously observed calcium leakage from L-SR vesicles. Therefore, the volatile anaesthetic-induced increase in calcium leakage in L-SR vesicles must be mediated via other pathways involving membrane proteins. (*Br. J. Anaesth.* 1997; **78**: 66–74)

**Key words**
Ions, calcium. Ions, ion channels. Anaesthetics volatile. Membrane, lipid bilayer. Theories of anaesthetic action, lipid bilayer.

The volatile anaesthetics halothane, enflurane and isoflurane alter calcium homeostasis in many cells. Volatile anaesthetics alter cellular $Ca^{2+}$ in part by acting on the sarcoplasmic reticulum (SR). They have been shown to increase the rates of $Ca^{2+}$ release[1–5] and of $Ca^{2+}$ uptake[5 6] from the SR. The former effect results from a volatile anaesthetic-induced increase in the open probability of calcium release channels,[7] increase in the rate of ATP breakdown[1 5] and decrease in SR calcium pump activity.[8–10] The increase in the rate of $Ca^{2+}$ uptake results from an increase in SR calcium pump activity when volatile anaesthetics are present at low concentrations.[1 5 9] Volatile anaesthetics also increase $Ca^{2+}$ leakage in vesicles isolated from the light SR (L-SR), which lacks calcium release channels.[1] The latter effect might be caused by a volatile anaesthetic action on the SR lipid membrane, enhancement of leakage pathways through membrane proteins or action on the interface between membrane lipids and proteins.

We have investigated one of these possibilities, the effect of volatile anaesthetics on $Ca^{2+}$ permeability of SR lipid membranes. It has been shown previously in liposomes that halothane increases membrane permeability to monovalent cations ($K^+$, $Rb^+$) and protons.[11 12] Therefore, it is expected that volatile anaesthetics should also increase $Ca^{2+}$ permeability of lipid membranes. Using the planar lipid bilayer system, we have investigated to what extent volatile anaesthetics affected $Ca^{2+}$ permeability of lipid membranes formed with either synthetic or L-SR-extracted lipids. We found that at the concentrations studied, volatile anaesthetics did not affect membrane-specific capacitance or ionic selectivity but significantly increased overall membrane ionic permeability (up to 10-fold). However, the magnitude of this increase was too small to account for the previously observed volatile anaesthetic-induced increase in $Ca^{2+}$ leakage in isolated L-SR-vesicles.

## Materials and methods

### LIPID COMPOSITION OF PLANAR LIPID BILAYERS

Two mixtures of synthetic lipids were used: one consisted of a mixture of the neutral lipids palmitoyl-linoleoyl phosphatidylcholine, palmitoyl-arachidonyl phosphatidylethanolamine and cholesterol at a molar fraction of 7.5:2.5:1. This ratio was chosen to mimic the reported lipid composition of muscle SR.[13 14] The second lipid mixture contained the same components as the first mixture and 10% phosphatidylinositol. The latter was selected because SR lipids contain negatively charged phospholipids (approximately 10%), the main one being phosphatidylinositol.[13 15] Lipids were purchased from Avanti Polar Lipids, Inc. The lipid mixture was dissolved in decane (5% w/v) to form planar–lipid bilayers, as described previously.[16]

L-SR vesicles were isolated from rabbit skeletal muscle,[1] resuspended with distilled water (approximately 8.3 mg protein/ml) and lyophilized. Lipids were extracted[17 18] and stored in chloroform/methanol (2/1) at −20°C. The phospholipid content was measured by a phosphorus assay.[19] The phosphorus content of lipid extract was 0.72 mm/mg SR protein. To form planar–lipid bilayers, the chloroform–methanol was evaporated and the lipids dissolved in decane (5% w/v). Decane was used as it has been shown that it has little effect on blocking nerve impulses and on membrane thickness.[20] The data shown were obtained using a single preparation of L-SR-extracted lipids. Other L-SR-extracted lipid preparations were used in pilot experiments.

The bilayer chamber contained two compartments (1.24 ml capacity) separated by a partition with a hole (0.2–1.0 mm diameter) where lipid bilayers were formed. The front and back compartments are referred to as *cis* and *trans*, respectively. Silver–silver chloride electrodes were placed in each compartment; the reference electrode was placed in the *trans* compartment. The compartments contained 1 ml of a given solution. Salt bridges were not used during the experiments with $CaCl_2$ solutions. When asymmetrical $CaCl_2$ solutions were used, the applied potential was corrected for the estimated electrode–liquid potential differences.[21] For the experiments using sucrose solution, KCl 3 mol litre$^{-1}$ salt bridges were used to stabilize the electrode offset.

### MEMBRANE CONDUCTANCE AND CAPACITANCE MEASUREMENTS

Total membrane conductance ($g_m$), that is conductance caused by all ion species present in the solution, was measured using symmetrical solutions of $CaCl_2$ 200 mmol litre$^{-1}$. Slope conductances were obtained from linear fits of the current–voltage relationships constructed by applying 25-mV voltage steps between +50 and −50 mV. Holding potentials were maintained for 1–2 min to eliminate the contribution of slow capacitive currents. Membrane capacitances were calculated by measuring capacitive currents after applying 1-mV triangular voltage steps at a frequency of 100 Hz. Membranes were seen with a 120-times magnification and their diameter, limited by a visible torus, was measured with a graduated grid (2.5 μm/division). Membrane surface area was calculated assuming that the shape of the membrane was an ellipse. All solutions contained HEPES 2 mmol litre$^{-1}$ at pH 6.0. Free acid HEPES of the best grade was used (Sigma Chemical Co., St Louis, MO, USA). We used a pH value of 6.0 to reduce proton–hydroxide conductance ($g_{H^+OH^-}$).[22]

Total membrane conductance ($g_m$) was measured using symmetrical solutions of $CaCl_2$ 0.2 mol litre$^{-1}$. In all cases it was assumed that the conductance caused by the anion form of HEPES was negligible.

### DIFFUSION POTENTIAL MEASUREMENTS AND ESTIMATIONS OF TRANSFERENCE NUMBER

To obtain the relative membrane ionic selectivity for calcium over chloride, we estimated the transference number of $Ca^{2+}$ ($t_{Ca}$) by measuring diffusion potentials as described previously.[22–24] The zero current level was first measured in symmetrical $CaCl_2$ 20 mmol litre$^{-1}$ by applying 0 mV. The concentration of $CaCl_2$ was then increased in the *cis* compartment in a stepwise manner to 60, 120 and 200 mmol litre$^{-1}$ by addition of $CaCl_2$ 1 mol litre$^{-1}$, and the potential required to re-establish the zero current level (diffusion potential) was determined by interpolation of the current measurements obtained at 2–3 different membrane potentials. Changes in diffusion potential were obtained at every dose of volatile anaesthetic for membranes formed with synthetic lipids, and at the median and high doses of volatile anaesthetics for membranes formed with L-SR-extracted lipids. The $t_{Ca}$ was calculated by equation (1), assuming that only $Ca^{2+}$ and $Cl^-$ ions carried the ionic current (see Appendix for derivation).

$$V_d = (1 - 1.5t_{Ca}) \times (RT/F) \times \ln (a_{cis}/a_{trans}) \quad (1)$$

where $V_d$=measured diffusion potential, $R$=gas constant, $T$=temperature in Kelvin, $F$=Faraday constant, $a_{cis}$=mean salt activity of *cis* chamber and $a_{trans}$=mean salt activity in *trans* chamber. Values for mean salt activity were interpolated from previously reported values.[25] In most cases, $t_{Ca}$ values were estimated using a 10-fold concentration gradient. In some cases, $t_{Ca}$ values were obtained using a six-fold concentration gradient.

### ADDITION OF VOLATILE ANAESTHETICS AND MEASUREMENT OF VOLATILE ANAESTHETIC CONCENTRATIONS

Stock solutions of saturated volatile anaesthetics were prepared[1] in either sucrose 0.6 mol litre$^{-1}$, $CaCl_2$ 20 mmol litre$^{-1}$ or $CaCl_2$ 200 mmol litre$^{-1}$. A small volume (20–100 μl) of the bath solution was first removed and then replaced by an equal volume of the bath solution saturated with a volatile anaesthetic. After each addition of volatile anaesthetic (to both compartments), the chamber compartments were covered with glass coverslips and solutions stirred continuously for 1 min. The volatile anaesthetic concentration in the stock and chamber solutions was determined by gas chromatography.[26]

*Table 1* Estimated values for the hypothetical MAC at 25 °C (H-MAC) and the corresponding hypothetical aqueous concentration at 25 °C (H-$EC_{50}$). H-MAC and H-$EC_{50}$ were obtained using equations (2) and (3) as described under materials and methods

| | MAC(30) (37 °C) | H-MAC (25 °C) | H-$EC_{50}$ (25 °C) |
|---|---|---|---|
| Isoflurane | 2 1% | 0 93% | 0.47 |
| Halothane | 1.4% | 0.62% | 0.32 |
| Enflurane | 2.9% | 1.29% | 0.66 |

As experiments were performed at room temperature (approximately 25 °C), the magnitude of volatile anaesthetic effects at 37 °C are uncertain. To attempt a comparison of the relative potency of the volatile anaesthetics, we also present the volatile anaesthetic concentration as the ratio of the hypothetical aqueous concentration (H-$EC_{50}$) corresponding to the hypothetical MAC at 25 °C. This was done in the following way. First, we estimated the hypothetical MAC value at 25 °C (H-MAC (25 °C)) using equation (2) derived from Franks and Lieb.[27]

$$\text{H-MAC } (Tc)/\text{MAC } (37\,°\text{C}) = \exp\left(-20.2\,(37-Tc)/(273.15+Tc)\right) \qquad (2)$$

Then, using H-MAC (25 °C) we estimated the corresponding hypothetical aqueous concentrations (mmol litre$^{-1}$) (H-$EC_{50}$) using equation (3).[27]

$$\text{H-}EC_{50}\ (\text{mmol litre}^{-1}) = 0.44614\,\alpha\text{MAC } (\%) \qquad (3)$$

where $\alpha$=Bunsen water/gas partition coefficient. At 25 °C, $\alpha$ values are similar for halothane (1.20) and isoflurane (1.08),[28] but there is no reported value for enflurane. As the three volatile anaesthetics have similar $\alpha$ values at 37 °C,[28 29] we assumed that this also held true at 25 °C, and used a mean $\alpha$ value of 1.14 for all three volatile anaesthetics. We used MAC values from rabbits[30] as the extracted SR lipids were from rabbit skeletal muscle (table 1).

*Table 2* Membrane areas and specific capacitance values for membranes formed with synthetic neutral lipids (Synthetic) and with L-SR-extracted lipids (L-SR) in the absence and presence of volatile anaesthetic (mean (SEM)). (In all cases the partition hole was 0.2 mm in diameter)

| Enflurane 1.88 | 0.90 (0.23) | 0.89 (0.25) | 4 |

### STATISTICS

Results are presented as mean (SEM). Differences between values obtained from synthetic and L-SR-extracted lipids in the absence of anaesthetic were analysed using the Mann–Whitney rank sum test. Differences between control and anaesthetics values were analysed by Friedman's test followed by the non-parametric Dunnett's test based on rank sum as *post hoc* analysis. In all cases, $P<0.05$ was considered significant.

## Results

### SPECIFIC CAPACITANCE

Under control conditions, membranes formed with L-SR-extracted lipids were smaller and had higher specific capacitance values than membranes formed with synthetic lipids (tables 2, 3). Such differences could reflect the presence of negatively charged phospholipids, as membranes formed with synthetic lipids containing negatively charged phospholipids had membrane areas and specific capacitance values resembling those of membranes formed with L-SR-extracted lipids (table 3).

*Table 3* Electrical properties and calculated calcium permeability in membranes formed with synthetic and L-SR-extracted lipids (mean (SEM)). $n$=number of membranes. For synthetic neutral lipids $n$=15 except for $t_{Ca}$ and $g_{msucr}$, $n$=4 For L-SR-extracted lipids, $n$=16 except for $t_{Ca}$, $n$=3. *Figure 1* Current–voltage relationships of membranes formed with synthetic neutral lipids measured in the presence of $CaCl_2$ 200 mmol litre$^{-1}$ before and after addition of isoflurane. Each point represents the mean value from 3–5 membranes, in the absence (■) and presence of isoflurane 0.72 mmol litre$^{-1}$ (◆) and 0.92 mmol litre$^{-1}$ (●). Inset shows the current–voltage relationship for control at an expanded scale. The lines represent linear regression fits for each condition and have the following values: $y=0.005x-0.001$, $r^2=0.998$ for control; $y=0.187x-0.113$, $r^2=1.000$ for isoflurane 0.72 mmol litre$^{-1}$ and $y=0.901x-0.333$, $r^2=1.000$ for isoflurane 0.92 mmol litre$^{-1}$

The area and specific capacitance of membranes formed with synthetic or L-SR-extracted lipids were not changed significantly by isoflurane, halothane or enflurane (table 2). Therefore, within the concentration range studied, these volatile anaesthetics did not affect membrane dimensions (area and specific capacitance).

## TOTAL MEMBRANE CONDUCTANCE IN $CACL_2$

In the absence and presence of anaesthetic, current–voltage relationships were linear from +50 to −50 mV (fig. 1). $g_m$ was significantly higher in membranes formed with L-SR-extracted lipids than in membranes formed with synthetic neutral lipids (table 3). When phosphatidylinositol was added to the mixture of lipids, $g_m$ values were between those for membranes formed with synthetic neutral lipids and L-SR-extracted lipids (table 3). All three volatile anaesthetics increased $g_m$ in a dose-dependent manner; in all cases, the dose–response curves were linear with the log of $g_m$ (fig. 2). The strongest effect was shown by isoflurane and the weakest effect by halothane; the effect of enflurane was intermediate. The magnitude of the volatile anaesthetic-induced increase in $g_m$ was lower in membranes formed with L-SR-extracted lipids than in membranes formed with synthetic lipids.

## TRANSFERENCE NUMBER FOR CALCIUM

In order to determine the ionic selectivity of membrane

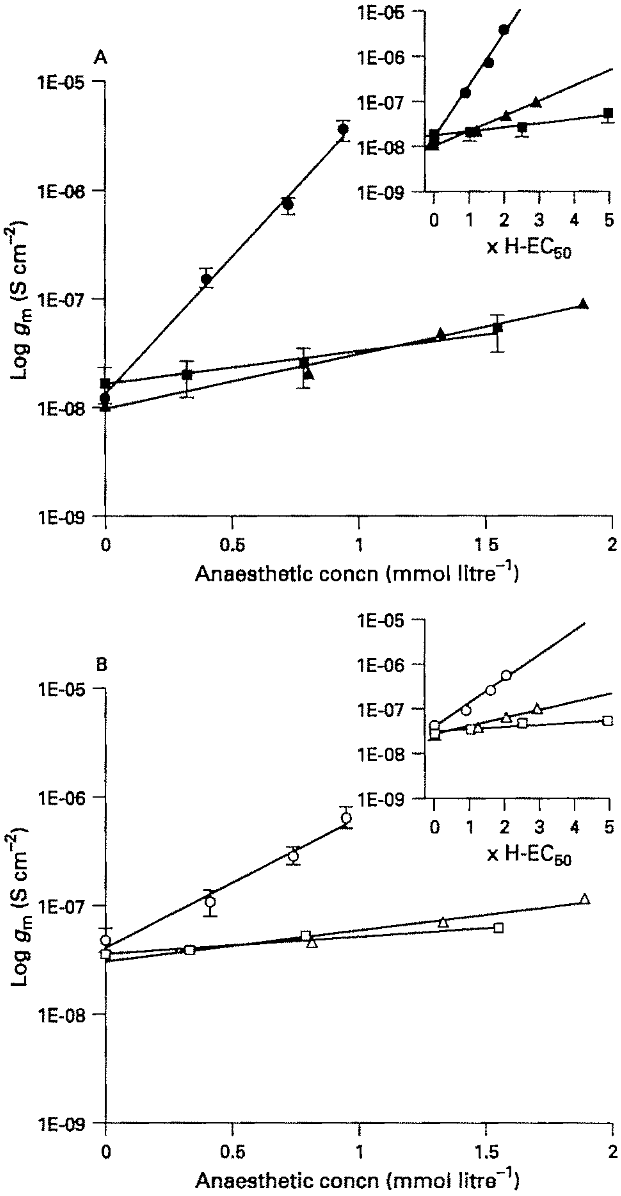

*Figure 2* Effects of volatile anesthetics on total specific membrane conductance. Total specific membrane conductance ($g_m$) measurements were performed in symmetrical solutions of $CaCl_2$ 200 mmol litre$^{-1}$ in membranes formed with synthetic neutral lipids (A) and with L-SR-extracted lipids (B). The anaesthetic concentration in the aqueous solution is given in mmol litre$^{-1}$ and as the ratio of the hypothetical-aqueous concentration (H-$EC_{50}$) corresponding to the hypothetical MAC at 25°C (insets). The data were fitted to a single exponential function. The fits of the data collected in membranes formed with synthetic lipids gave the following values: $y=1.31\times10^{-8}\times10^{2.53\times X}$ ($r^2=0.99$), $y=1.60\times10^{-8}\times10^{0.31\times X}$ ($r^2=0.97$), and $y=0.98\times10^{-8}\times10^{0.50\times X}$ ($r^2=0.99$) for isoflurane (●) (six membranes), halothane (■) (four membranes) and enflurane (▲) (five membranes), respectively for log $g_m$ *vs* mmol litre$^{-1}$; and $y=1.31\times10^{-8}\times10^{1.19\times X}$ ($r^2=0.99$), $y=1.60\times10^{-8}\times10^{0.10\times X}$ ($r^2=0.97$) and $y=0.98\times10^{-8}\times10^{0.33\times X}$ ($r^2=0.99$) for isoflurane, halothane and enflurane, respectively for log $g_m$ *vs* xH-$EC_{50}$. The fits of the data collected in membranes formed with L-SR-extracted lipids gave the following values: $y=4.27\times10^{-8}\times10^{1.20\times X}$ ($r^2=0.99$), $y=3.56\times10^{-8}\times10^{0.17\times X}$ ($r^2=0.92$) and $y=3.17\times10^{-8}\times10^{0.28\times X}$ ($r^2=0.96$) for isoflurane (○) (six membranes), halothane (□) (six membranes) and enflurane (△) (four membranes), respectively, for log $g_m$ *vs* mmol litre$^{-1}$; and $y=4.27\times10^{-8}\times10^{0.56\times X}$ ($r^2=0.98$), $y=3.56\times10^{-8}\times10^{0.06\times X}$ ($r^2=0.92$) and $y=3.17\times10^{-8}\times10^{0.19\times X}$ ($r^2=0.96$) for isoflurane, halothane and enflurane, respectively for log $g_m$ *vs* xH-$EC_{50}$. The data points represent mean (SEM). The observed increases in $g_m$ were significant at all doses of volatile anaesthetic except that observed at the lowest dose of halothane in membranes formed with L-SR-extracted lipids.

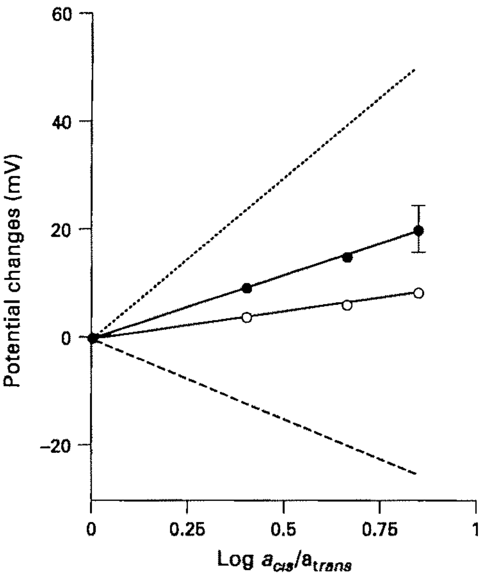

*Figure 3* Diffusion potentials in various $CaCl_2$ concentration gradients of membranes formed with synthetic neutral and L-SR-extracted lipids. Diffusion potentials were measured as described under materials and methods and plotted against the logarithmic ratio of salt activity of *cis* to *trans* solution. ●=Mean of four membranes formed with synthetic lipids and ○=mean of three membranes formed with L-SR-extracted lipids. The regression line gave the following values: $y=23.28\times x-0.008$ ($r^2=0.998$) and $y=9.72\times x-0.04$ ($r^2=0.999$) for synthetic and L-SR- extracted lipids, respectively. The Nerst potential values for $Cl^-$ (dotted line) and $Ca^{2+}$ (broken line) are indicated Data points are mean (SEM). Lipid membranes were initially formed in symmetrical $CaCl_2$ 20 mmol $litre^{-1}$, then the concentration of $CaCl_2$ in the *cis* compartment was increased. Membrane potential ($V_m$) was obtained by adding to the command potential ($V_{cmd}$) estimated electrode–liquid potential differences ($E_R$) (−20.1, −32.2 and −40.1 mV for 60/20, 120/20 and 200/20 mmol $litre^{-1}$ of $CaCl_2$, *cis/trans*) (e.g. in $CaCl_2$ 60/20, gradient for $V_{cmd}=+50$ mV, $V_m=+50+(-20)=+30$ mV). $E_R$ results from the electrodes being exposed to different concentrations of $Cl^-$ and was calculated using the following expression. $E_R=-2.303(RT/F)\log(aCl^-_{cis}/aCl^-_{trans})$ where $aCl^-$=activity of $Cl^-$ in either the *cis* or *trans* compartments.[21 25]

*Table 4* Calcium transference number ($t_{Ca}$) in the absence and presence of volatile anaesthetic (mean (SEM)). $n=3$ membranes in all cases except for control with synthetic lipids where $n=4$ membranes

| Anaesthetic (mmol $litre^{-1}$) | Synthetic lipids $t_{Ca}$ | L-SR-extracted lipids $t_{Ca}$ |
|---|---|---|
| Control | 0.40 (0.02) | 0.56 (0.01) |
| Isoflurane 0.40 | 0.45 (0.03) | |
| Isoflurane 0.72 | 0 37 (0.02) | 0.56 (0.01) |
| Isoflurane 0.94 | 0.40 (0 03) | |
| Halothane 0.32 | 0.47 (0.08) | |
| Halothane 0 78 | 0.45 (0.02) | 0.48 (0.08) |
| Halothane 1.54 | 0.52 (0.05) | |
| Enflurane 0.80 | 0.51 (0.05) | |

| Enflurane 1.88 | 0.40 (0.01) | |

conductance, we estimated the transference number for calcium ($t_{Ca}=g_{Ca}/g_m$) by assuming that under the conditions measured, the only two permeant ions were $Cl^-$ and $Ca^{2+}$. This was done by measuring the diffusion potential at different $CaCl_2$ concentrations (see materials and methods). The diffusion potential was a linear function of the log of the activity ratio (log $a_{cis}/a_{trans}$) across the membrane in synthetic and

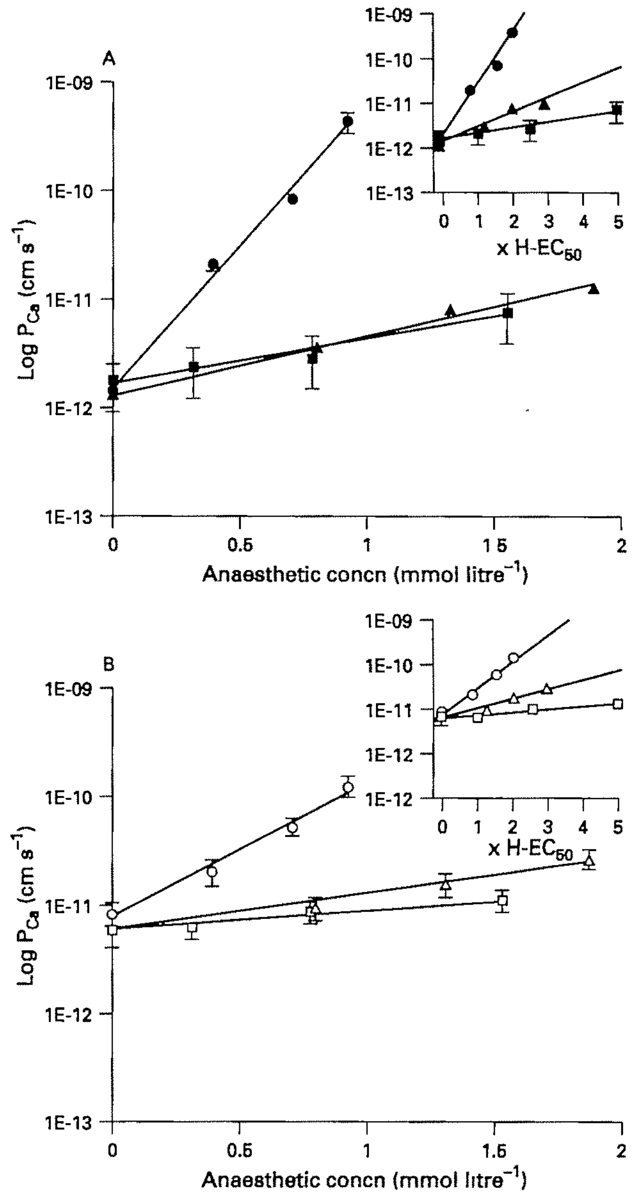

*Figure 4* Effect of volatile anaesthetics on calcium permeability in membranes formed with synthetic (A) and L-SR-extracted lipids (B). The log of membrane calcium permeability ($P_{Ca}$) was plotted against the anaesthetic concentration in the aqueous solution in mmol $litre^{-1}$ and against the ratio of the hypothetical-aqueous concentration (xH-$EC_{50}$) corresponding to the hypothetical MAC at 25°C (insets). The number of membranes used are the same as in figure 2. Data were fitted to a single exponential function. The fits of the data collected in membranes formed with synthetic lipids gave the following values: $y=1\ 66\times10^{-12}\times10^{2\ 49\times X}$ ($r^2=0.99$), $y=1.65\times10^{-12}\times10^{0\ 37\times X}$ ($r^2=0.97$), and $y=1.34\times10^{-12}\times10^{0\ 50\times X}$ ($r^2=0.99$) for isoflurane (●), halothane (■) and enflurane (▲), respectively, for log $P_{Ca}$ *vs* mmol $litre^{-1}$; and $y=1.66\times10^{-12}\times10^{1.17\times X}$ ($r^2=0.99$), $y=1.65\times10^{-12}\times10^{0\ 12\times X}$ ($r^2=0.97$) and $y=1.34\times10^{-12}\times10^{0\ 33\times X}$ ($r^2=0.99$) for isoflurane, halothane and enflurane, respectively, for log $P_{Ca}$ *vs* xH-$EC_{50}$. The fits of the data collected in membranes formed with L-SR-extracted lipids gave the following values: $y=7.39\times10^{-12}\times10^{1\ 20\times X}$ ($r^2=0.98$), $y=5.80\times10^{-12}\times10^{0\ 14\times X}$ ($r^2=0.87$) and $y=5.60\times10^{-12}\times10^{0\ 30\times X}$ ($r^2=0.97$) for isoflurane (○), halothane (□) and enflurane (△), respectively, for log $P_{Ca}$ *vs* mmol $litre^{-1}$; and $y=7.39\times10^{-12}\times10^{0\ 56\times X}$ ($r^2=0.98$), $y=5.80\times10^{-12}\times10^{0\ 04\times X}$ ($r^2=0.87$) and $y=5.60\times10^{-12}\times10^{0\ 20\times X}$ ($r^2=0\ 97$) for isoflurane, halothane and enflurane, respectively, for log $P_{Ca}$ *vs* xH-$EC_{50}$. Data points represent mean (SEM). The observed increases in $P_{Ca}$ were significant at all doses of volatile anaesthetic except that observed at the lowest dose of halothane in membranes formed with L-SR-extracted lipids.

L-SR-extracted lipids and intercepted 0 at both axes, as is expected for diffusion potentials (fig. 3). Figure 3 also indicates the diffusion potential for a purely chloride-selective membrane and a purely calcium-selective membrane. The diffusion potentials of membranes formed with synthetic lipids were closer to the values expected for a purely chloride-selective membrane than the diffusion potentials of membranes formed with L-SR-extracted lipids. In fact, the calculated $t_{Ca}$ value was larger in membranes formed with L-SR-extracted lipids than in membranes formed with synthetic lipids (table 3).

The volatile anaesthetics did not produce significant changes in $t_{Ca}$ (table 4). Therefore, volatile anaesthetics induced an increase in $g_m$ without changing the ionic selectivity of the membrane pathway. Figure 3 shows that the diffusion potential changed linearly with log $(a_{cis}/a_{trans})$, indicating that the $t_{Ca}$ values are similar at various concentration gradients.

### CALCIUM CONDUCTANCE AND PERMEABILITY OF LIPID MEMBRANES

Specific calcium conductance $(g_{Ca})$ and permeability $(P_{Ca})$ were estimated in $CaCl_2$ 200 mmol $litre^{-1}$ by assuming that the proton and hydroxide conductances were negligible, and by using equations (4) and (5):

$$g_{Ca}=g_m t_{Ca} \qquad (4)$$

$$P_{Ca}=RTg_{Ca}/(z^2F^2[Ca^{2+}]) \qquad (5)$$

where $z$=valence of calcium, $[Ca^{2+}]$=concentration of calcium (mol $cm^{-3}$). $g_{Ca}$ and $P_{Ca}$ values were approximately 4.5 times larger in membranes formed with L-SR-extracted lipids than in membranes formed with synthetic lipids (table 4). Volatile anaesthetics did not affect $t_{Ca}$ (table 4) but increased $P_{Ca}$ (fig. 4). The observed increase in $P_{Ca}$ was therefore caused by an increase in $g_m$ (fig. 2) rather than a change in ionic selectivity (table 4). Isoflurane produced the largest increase in $P_{Ca}$, the effects of enflurane and halothane were smaller.

### MEMBRANE CONDUCTANCE IN THE PRESENCE OF SUCROSE 0.6 MOL $LITRE^{-1}$

Total membrane conductance measured in $CaCl_2$ $(g_m)$ is the sum of the conductance for each ion present in the bath solution. We attempted to estimate the contribution of proton–hydroxide conductance to total membrane conductance by measuring membrane conductance in the presence of symmetrical solutions of sucrose 0.6 mol $litre^{-1}$. In the absence of volatile anaesthetic, $g_{msucr}$ and $g_m$ were the same (fig. 5). Isoflurane increased $g_{msucr}$ of membranes in a dose-dependent manner (fig. 5). However, the isoflurane-induced increase in $g_{msucr}$ was approximately 25% of the isoflurane-induced increase in $g_m$. This indicates that volatile anaesthetics induce an increase not only in $P_{H^+OH^-}$ but also in $P_{Ca}$ or $P_{Cl}$, or both. If one assumes that $g_{msucr}$ is only a result of $P_{H^+OH^-}$ then $g_m$ of these membranes in the absence of volatile anaesthetic should be entirely a result of $P_{H^+OH^-}$. This is unlikely as we were able to measure diffusion potentials in gradients of $CaCl_2$ and in the absence of a gradient for $H^+$ and $OH^-$. There are two possible explanations why in the absence of volatile anaesthetic, $g_m$ was equal to $g_{msuc}$. First, sucrose could increase $P_{H^+OH^-}$ and second, $CaCl_2$ could decrease $P_{H^+OH^-}$.

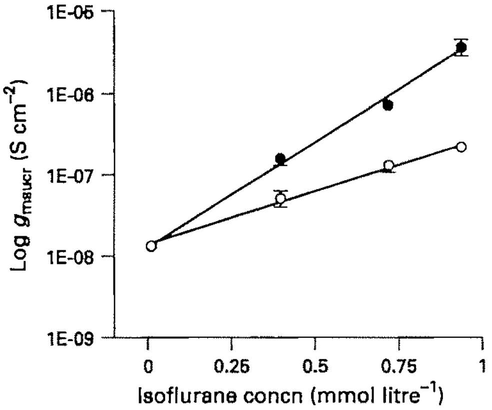

*Figure 5* Effect of isoflurane on total specific membrane conductance in sucrose. The total specific membrane conductance in sucrose $(g_{msucr})$ was measured in symmetrical solutions of sucrose 0.6 mol $litre^{-1}$ in membranes formed with synthetic lipids (electrodes with salt bridges). $g_{msucr}$ was plotted against the anaesthetic concentration in the bath solution (mmol $litre^{-1}$). Data were fitted to a single exponential function. The fits of the data collected in sucrose 0 6 mol $litre^{-1}$ (○) gave the following values: $y=1.43\times10^{-8}10^{1\ 28\times X}$ $(r^2=0.99)$ (four membranes). ●=Data collected in $CaCl_2$ solutions shown in figure 2A: $y=1.31\times10^{-8}\times10^{2\ 53\times X}$ $(r^2=0.99)$.

## Discussion

At the concentrations studied, we found that volatile anaesthetics increased $g_{Ca}$ and $g_{Cl}$ without affecting ionic selectivity or specific capacitance of planar lipid bilayers. We found also that volatile anaesthetics induced a significant increase in $P_{Ca}$ of lipid membranes, such an increase depended on the lipid composition, but its magnitude was too small to account for the previously reported volatile anaesthetic-induced increase in $Ca^{2+}$ leakage in isolated L-SR vesicles.

### MEMBRANE SPECIFIC CAPACITANCE

Membranes formed with L-SR-extracted lipids and synthetic lipids containing negatively charged phospholipids were smaller and had higher specific capacitance values than membranes formed with synthetic neutral lipids. Therefore, at least in the presence of high $Ca^{2+}$ concentrations, negatively charged phospholipids appear to be responsible, in part, for the formation of a larger membrane torus (smaller membrane area) and providing the membrane with a higher specific capacitance value.

A potential artefact in our capacitance measurements might result from residual decane in the lipid phase. This was unlikely because the specific capacitance values obtained in this study were similar to those reported previously for biological cell membranes.[31] Moreover, it has been reported that when actual membrane areas are measured, decane does not significantly affect membrane thickness and it appears to accumulate mainly at the membrane

*Table 5* Calcium currents ($I_{Ca}$) in the absence and presence of volatile anaesthetic *The concentrations of volatile anaesthetic were: halothane 1.54, enflurane 1.88 and isoflurane 0.94 mmol litre$^{-1}$. **This value was calculated using Ca$^{2+}$ leakage measurements from SR of skinned cardiac myocytes (1.24 mmol litre$^{-1}$)[33] in the absence of ATP and anaesthetic. It was assumed that cell volume was 24 pl, SR volume per myocyte was 8 4 pl and SR surface area per myocyte was 29 28×10$^3$ μm$^2$.[34] ***This value was calculated from Ca$^{2+}$ leakage measured in isolated L-SR-vesicles from skeletal muscle after ATP depletion.[1] It was assumed that 1 mg protein from L-SR membranes corresponded to 2.8×10$^3$ cm$^2$ SR membrane area[35]

| | $I_{Ca}$(mol cm$^{-2}$s$^{-1}$) |
|---|---|
| Synthetic lipid | $2.0\times10^{-17}$ |
| L-SR-extracted lipid | $8.3\times10^{-17}$ |
| L-SR-extracted lipid+halothane* | $11\ 2\times10^{-17}$ |
| L-SR-extracted lipid+enflurane | $26.5\times10^{-17}$ |
| L-SR-extracted lipid+isoflurane | $137.0\times10^{-17}$ |
| SR in skinned muscle cells** | $5.9\times10^{-13}$ |
| Isolated L-SR-vesicles*** | $3–11\times10^{-14}$ |

torus.[20] The lack of a volatile anaesthetic effect on either membrane area or specific capacitance indicates that, at the concentrations studied, volatile anaesthetics did not affect membrane geometry.

## MEMBRANE CONDUCTANCE AND $\mathrm{T_{Ca}}$ VALUES

Total membrane conductance ($g_m$) and Ca$^{2+}$ selectivity ($t_{Ca}$) was higher in membranes formed with L-SR-extracted lipids than in membranes formed with synthetic neutral lipids. This difference reflects, in part, the presence of negatively charged lipids in the L-SR-extracted lipid preparation, as $g_m$ and $t_{Ca}$ values were higher in membranes formed with synthetic lipids containing negatively charged lipids than in those containing only neutral lipids (table 3). The higher $t_{Ca}$ value is consistent with previous observations that lipid membranes become more cationic-selective when they have negatively charged lipids.[24]

At the concentrations studied, volatile anaesthetics increased $g_m$ without changing the $t_{Ca}$ value of the membrane, that is volatile anaesthetics increased the rate of ion transport across the lipid membrane pathway without affecting the ionic selectivity of such a pathway. As there were no membrane proteins present, ion transport across these membranes must be determined by lipid interactions. Our study, however, did not allow the molecular mechanism of these interactions in the presence of volatile anaesthetics to be defined.

## ESTIMATION OF Ca LEAKAGE CURRENTS

The magnitude of the Ca$^{2+}$ leakage currents were estimated using the Goldman flux equation,[32] and by assuming that the transmembrane potential across the SR membrane was 5 mV, intraluminal and cytoplasmic Ca$^{2+}$ concentrations were 10 mmol litre$^{-1}$ and 0.1 μmol litre$^{-1}$, respectively, and that $P_{Ca}$ was not affected by changes in Ca$^{2+}$ ion concentration.

$$I_{Ca}=(-P_{Ca}2FE_m/RT)\times([Ca^{2+}]_m-[Ca^{2+}]_{out})\times \exp(-2FE_m/RT)/(1-\exp(-2FE_m/RT)$$

where $I_{Ca}$=Ca$^{2+}$ flux (mol cm$^{-2}$ s$^{-1}$), $E_m$= transmembrane potential (V) and $[Ca^{2+}]_m$ and $[Ca^{2+}]_{out}$=intraluminal and myoplasmic Ca$^{2+}$ concentrations (mol cm$^{-3}$), respectively. The estimated $I_{Ca}$ for lipid membranes are three or four orders of magnitude smaller than those estimated for SR in skinned cardiac myocytes[33] (table 5). The high Ca$^{2+}$ leakage value of SR in skinned cardiac myocytes could reflect the presence of non-selective ion channel proteins. Non-selective chloride channels that allow passage of Ca$^{2+}$ ions and contribute significantly to Ca$^{2+}$ leakage have been demonstrated in isolated SR vesicles.[36] If Ca$^{2+}$ leakage through the SR in intact cells is as high as that reported for SR in skinned cells, then the observed volatile anaesthetic-induced increase in ionic permeability of lipid membranes will not contribute significantly to the overall SR leakage currents.

Estimated Ca$^{2+}$ leakage from isolated L-SR-vesicles[1] was two or three orders of magnitude higher than that estimated for lipid membranes in the absence and presence of volatile anaesthetics (table 5). Measurements were performed at room temperature in lipid membranes (this study) and at 37 °C in isolated L-SR vesicles.[1] However, such differences in temperature are unlikely to account for the different Ca$^{2+}$ leakage values. In fact, it has been reported that in liposomes formed with SR-extracted lipids, increasing the temperature from 25 to 40 °C increased the rate constant of Ca$^{2+}$ efflux by less than one order of magnitude.[37] As discussed in the next section, our estimated $P_{Ca}$ values for lipid membranes, if anything, represent overestimations because of the differences in other experimental conditions (e.g. calcium concentration, pH, etc.). Therefore, Ca$^{2+}$ leakage from isolated L-SR vesicles, both in the absence and presence of volatile anaesthetic, involves paths other than SR membrane lipids. These paths may involve inhibition of Ca$^{2+}$ pump activity, Ca$^{2+}$ efflux through membrane proteins such as the Ca$^{2+}$ pump (slippage through ATPase channels)[19] or through ion channels other than Ca$^{2+}$ release channels (e.g. non-selective ion channels),[36] or Ca$^{2+}$ leakage through the protein–lipid interface (boundary lipids).

The volatile anaesthetic-induced increase in $P_{Ca}$ of lipid bilayers and in Ca$^{2+}$ leakage from L-SR vesicles showed different properties. While volatile anaesthetics increased the $P_{Ca}$ of lipid bilayers in a dose-dependent manner, such dose dependency was not observed for the volatile anaesthetic-induced increase in Ca$^{2+}$ leakage from L-SR vesicles. The volatile anaesthetic-induced increase in $P_{Ca}$ of lipid bilayers was greater for isoflurane than for halothane or enflurane. This potency difference was not observed for the volatile anaesthetic-induced increase in Ca$^{2+}$ leakage from L-SR vesicles. Therefore, the volatile anaesthetic-induced increase in $P_{Ca}$ of membranes formed with L-SR-extracted lipids did not appear to be directly responsible for the volatile anaesthetic-induced increase in non-specific Ca$^{2+}$ leakage from isolated L-SR vesicles. Indirectly, however, the observed volatile anaesthetic-induced increase in membrane $P_{Ca}$ may serve as a trigger to activate calcium release channels; the volatile anaesthetic-induced increase in SR membrane chloride permeability may increase the activation of non-selective ion channels,[36] and the $Ca^{2+}$ currents through these non-selective channels may also serve as a trigger for calcium release channels.

### EFFECTS OF THE EXPERIMENTAL CONDITIONS AND ASSUMPTIONS ON THE ESTIMATED $P_{Ca}$

In this study several assumptions were made when estimating $P_{Ca}$. First, that increases in $Ca^{2+}$ did not affect the $P_{Ca}$ of lipid membranes. At high concentrations $Ca^{2+}$ is known to bind to phospholipids and produce phase separation of lipid mixtures.[38–40] To our knowledge, however, there are no reports indicating that increases in $Ca^{2+}$ affect the $P_{Ca}$ of lipid membranes. Such increases in $Ca^{2+}$ would not be expected to decrease $P_{Ca}$, if anything they may increase $P_{Ca}$. Second, we used pH 6.0 to reduce proton conductance through lipid membranes. Changes in pH are known to strongly affect the function of membrane proteins, however, our experiments were performed in the absence of membrane proteins. In the absence of membrane proteins, ions permeate only through the lipid membrane. If $H^+$ and $Ca^{2+}$ are using the same lipid pathway, reduction of protons should lead to an increase in the conduction of calcium. In this case, $P_{Ca}$ is overestimated when using a low pH. Third, the assumption that $g_{HEPES}$ was negligible compared with $g_{Ca}$ and $g_{Cl}$ and the lack of correction for the contribution by $g_{H/OH}$ tends to overestimate the calculated $P_{Ca}$. The presence of decane in the lipid membranes should increase $P_{Ca}$. All of the above assumptions tend to overestimate $P_{Ca}$. In spite of this, our estimated control $P_{Ca}$ values agreed closely with those obtained with $Ca^{2+}$ flux measurements in liposomes formed with various phospholipids or SR-lipid extracts, in which low concentrations of $Ca^{2+}$ were used (1 mmol $litre^{-1}$), no decane was present, pH was 8.0 and flux measurements were not contaminated by $g_{H/OH}$.[37] These observations suggest that in the absence of proteins our estimated $P_{Ca}$ values were close to those obtained using lipid vesicles at low calcium concentration and pH 8.0,[37] and that under our conditions the contribution of $g_{H/OH}$ was not significant. Even if there is overestimation of $P_{Ca}$, our main conclusion remains valid, that is that the volatile anaesthetic-induced increases in $P_{Ca}$, although significant, were too small to account for the previously observed volatile anaesthetic-induced increases in $Ca^{2+}$ leakage in skinned SR and isolated L-SR vesicles (table 5). Therefore, membrane paths other than SR membrane lipids must be involved.

In SR membranes, plasmalogens (alkyl ester phospholipids) account for 72% of phosphatidylethanolamine (PE) and 12% of phosphatidylcholine (PC) (20% of total phopholipids).[14] In this study we used diacyl PE and PC because plasmalogens were not available commercially. To our knowledge there are no reports on how plasmalogens affect membrane ionic permeability. It is possible, therefore, that the presence of plasmalogens in membranes formed with L-SR-extracted lipids contributes in part to the differences observed between membranes formed with synthetic lipids and L-SR-extracted lipids.

Halothane which, of the volatile anaesthetics studied, is the most potent trigger of malignant hyperthermia, produced the smallest increase in $g_{Ca}$ of lipid membranes and hence the smallest predicted increase in cytoplasmic $Ca^{2+}$. The latter suggests that the halothane-induced increase in $P_{Ca}$ of SR lipid membranes by itself does not appear to account for halothane-induced malignant hyperthermia.

In summary, at the concentrations studied, volatile anaesthetics increased the rate of ion transport across lipid membranes without affecting the ionic selectivity of the membrane or its dimensions. The strongest effect was exhibited by isoflurane and the weakest effect by halothane; the effect of enflurane was intermediate. This volatile anaesthetic effect cannot account for the volatile anaesthetic-induced increase in $Ca^{2+}$ leakage observed in isolated L-SR vesicles.

## Appendix

In our $CaCl_2$ solutions, the diffusion potential ($V_d$) or potential at which the current equals zero, was determined by the following equation:

$$V_d = g_{Ca}E_{Ca}/g_m + g_{Cl}E_{Cl}/g_m + g_{H/OH}E_{H/OH}/g_m + g_{HEPES}E_{HEPES}/g_m \quad (1)$$

where $g_{Ca}$=calcium conductance; $g_{Cl}$=chloride conductance; $g_{H/OH}$=proton–hydroxide conductance; $g_{HEPES}$=HEPES conductance; $E_{Ca}$, $E_{Cl}$, $E_{H/OH}$ and $E_{HEPES}$=equilibrium potentials (Nernst potential) for each of the ions As there was no pH or HEPES gradient, $E_{H/OH}$ and $E_{Hepes}$ are zero, and equation (1) becomes

$$V_d = t_{Ca}E_{Ca} + t_{Cl}E_{Cl} \quad (2)$$

where $t_{Ca}$=transference number for $Ca^{2+}$ and $t_{Cl}$=transference number for $Cl^-$ This equation can be rewritten as follows

$$V_d = -t_{Ca}\times(RT/2F)\times\ln([Ca^{2+}]_{cis}/[Ca^{2+}]_{trans}) + t_{Cl}(RT/F)\times\ln([Cl^-]_{cis}/[Cl^-]_{trans}) \quad (3)$$

$$V_d = (t_{Cl} - t_{Ca}/2)(RT/F)\times\ln([CaCl_2]_{cis}/[CaCl_2]_{trans}) \quad (4)$$

$$V_d = (t_{Cl} - t_{Ca}/2)(RT/F)\times\ln(a_{cis}/a_{trans}) \quad (5)$$

where $R$=gas constant; $T$=temperature in Kelvin scale, $F$=Faraday constant; $[]_{cis}$ and $[]_{trans}$=ion or salt concentration in the *cis* (front) and *trans* (back) compartments; $a_{cis}$ and $a_{trans}$=mean salt activity in the *cis* and *trans* compartments (interpolated from previously published values).[25] When assuming that only $Ca^{2+}$ and $Cl^-$ ions carry the current, then·

$$t_{Ca} + t_{Cl} = 1 \quad (6)$$

and equation (5) becomes·

$$V_d = (1 - 1.5t_{Ca})\times(RT/F)\times\ln(a_{cis}/a_{trans}) \quad (7)$$

# Effects of magnesium sulphate on atrioventricular conduction times and surface electrocardiogram in dogs anaesthetized with sevoflurane

S. AKAZAWA, R. SHIMIZU, Y. NAKAIGAWA, R. ISHII, S. IKENO AND R. YAMATO

## Summary

We have studied the effects of magnesium on atrioventricular (AV) conduction times and surface electrocardiogram during both sinus rhythm and atrial pacing in seven dogs anaesthetized with 1 MAC of sevoflurane. A bolus dose of magnesium sulphate ($MgSO_4$) 30, 60 and 90 mg kg$^{-1}$ significantly increased plasma magnesium concentrations from 1.3 (SEM 0.1) to 15.3 (1.3) mg dl$^{-1}$. $MgSO_4$ significantly prolonged A-H (AV nodal conduction time during sinus rhythm), St-H (intra-atrial and AV nodal conduction time during atrial pacing) and H-S (total ventricular conduction time) intervals at doses $\geq$30 mg kg$^{-1}$ ; H-V interval (His–Purkinje conduction time) at doses $\geq$60 mg kg$^{-1}$; RR and PR intervals and QRS duration at doses $\geq$30 mg kg$^{-1}$ in a dose-related manner during both sinus rhythm and atrial pacing. QTc interval remained unchanged during sinus rhythm. The doses of $MgSO_4$ used did not have deleterious effects on AV conduction times and surface electrocardiogram during 1 MAC of sevoflurane anaesthesia. This finding suggests that $MgSO_4$ in high doses was safe and may be indicated for cardiac arrhythmia and hypertension during sevoflurane anaesthesia. However, further study is required to apply these findings to clinical anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 000–000)

**Key words**
Anaesthetics volatile, sevoflurane. Heart, conduction. Monitoring, electrocardiography. Pharmacology, magnesium sulphate.

Magnesium has been used i.v. for several decades for the treatment of cardiac arrhythmias, such as paroxysmal atrial tachycardia, atrial fibrillation and ventricular extrasystoles associated with digitalis intoxication[1–3] and it has also been shown to be an effective anti-arrhythmic in a variety of cases of QT interval prolongation and torsades de pointes.[4 5] Recently, magnesium sulphate has been reported to have cardiac electrophysiological effects that explain its ability to suppress bupivacaine-induced cardiac arrhythmias in dogs.[6]

Inhalation anaesthetics affect specialized atrioventricular (AV) conduction: enflurane and halothane are more depressant on AV conduction times than isoflurane.[7] The electrophysiological effects of sevoflurane, however, have not been examined fully. Comparing the effects of 1 and 2 MAC of sevoflurane, isoflurane and halothane on specialized AV conduction times in dogs anaesthetized with pentobarbitone, we have found previously that both sevoflurane and isoflurane did not affect AV conduction times, whereas halothane significantly prolonged atrio-His conduction time.[8]

Magnesium salts could be used during inhalation anaesthesia because of their anti-arrhythmic and antihypertensive properties. Although the electrophysiological and electrocardiographic effects of i.v. administered magnesium salts have been studied in animals[9 10] and in humans,[11 12] the effects of magnesium on the cardiac conduction system have not been studied during inhalation anaesthesia. Therefore, we have investigated the effects of magnesium sulphate on AV conduction times and surface electrocardiogram in dogs anaesthetized with sevoflurane.

## Materials and methods

### ANIMAL PREPARATION

The study was approved by the management committee at the Jichi Medical Laboratory of Experimental Medicine, based on the school's *Guide for Laboratory Animals*, 1993.

Anaesthesia was induced in seven mongrel dogs, weighing 13–18 kg, with 3-5% sevoflurane via a funnel-shaped plastic mask fitted to the dog's face and connected to a Jackson–Rees circuit. The trachea was intubated without neuromuscular blocking agents and ventilation was adjusted to maintain normocapnia with a Harvard pump respirator (R-60, Aika, Co., Ltd). Anaesthesia during surgical preparation was maintained with 2–3% end-tidal concentrations of sevoflurane and 50% nitrous oxide in oxygen delivered into an inspiratory limb of a Harvard pump respirator. Sevoflurane was vaporized

Correspondence to S A.

with a Sevotec vaporizer (Penlon Inst., Ltd) and end-tidal concentrations of sevoflurane were measured with a calibrated respiratory gas analyser (Model 5250, Ohmeda). A micromanometer-tipped catheter (7F 45326, Toyoda Instr, Ltd) was placed through the left femoral artery into the abdominal aorta to measure systolic, diastolic and mean arterial pressures (SAP, DAP and MAP, respectively). A catheter was inserted into the abdominal aorta via the right femoral artery to sample arterial blood for measurement of pH, $Pa_{O_2}$, $Pa_{CO_2}$, and serum $Na^+$, $K^+$ and $Ca^{2+}$ concentrations (288 Blood Gas System, Ciba Corning). Plasma total magnesium and calcium concentrations were measured by colorimetric assay. Lactated Ringer's solution was infused at 5–10 ml $kg^{-1}$ $h^{-1}$ into the left femoral vein throughout the experiment. Arterial blood pH was adjusted to the normal range by i.v. administration of sodium bicarbonate. KCl solution was given to maintain serum $K^+$ concentration between 3.5 and 4.5 mmol $litre^{-1}$. Body temperature was measured with an oesophageal thermistor and maintained at 36–37 °C using an external heating blanket.

A 6F quadripolar electrode catheter was inserted via the left internal carotid artery and advanced towards the aortic root until a stable His-bundle electrogram (HBE) was obtained as displayed on an oscilloscope.[13] The His-bundle catheter electrodes were connected to a switch box that allowed selection of any combination of two electrodes. The output of the switch box was connected to a pre-amplifier with a bandwidth cut-off frequency of 40–1000 Hz. The electrodes of the surface ECG (lead II and $V_5$) were connected to another pre-amplifier with a filter bandwidth of 0.1–120 Hz. The output from each preamplifier was recorded onto a thermal recorder (8M15, NEC San-ei, Ltd, Tokyo, Japan) at a paper speed of 100 mm $s^{-1}$. Arterial pressures and surface ECG were recorded on a multi-channel recorder (Recti-Horiz-8K, NEC San-ei, Ltd, Tokyo, Japan). Heart rate was measured by counting QRS complexes over 10 s.

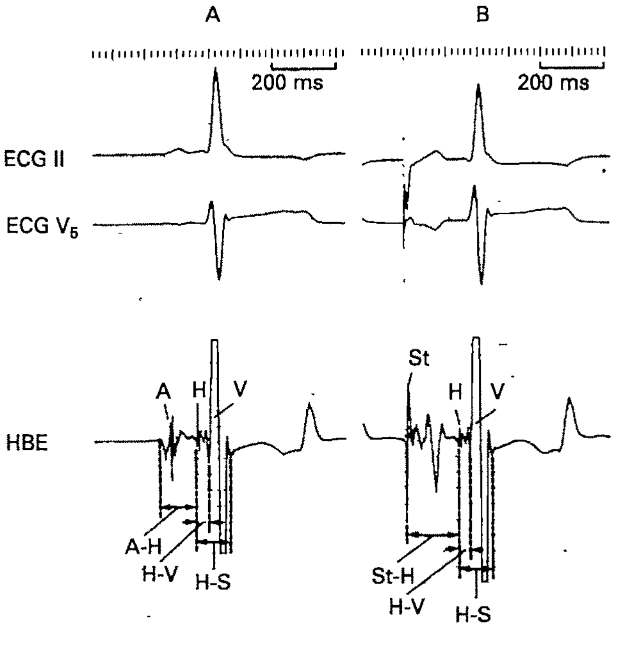

*Figure 1* Surface electrocardiograms (ECG) (leads II and $V_5$) and His-bundle electrogram (HBE) during sinus rhythm (A) and atrial pacing (B). A=Atrial deflection; H=His-bundle spike; V=ventricular deflection; St=stimulus artefact; A-H (atrioventricular (AV) nodal conduction time during sinus rhythm)=interval from atrial deflection to the beginning of the His-bundle spike in the HBE; St-H (intra-atrial and AV nodal conduction time during atrial pacing)=interval from stimulus artefact (St) to the beginning of the His-bundle spike in the HBE; H-V (His–Purkinje conduction time)=interval from the beginning of the His-bundle spike to the beginning of ventricular deflection in the HBE; H-S (ventricular conduction time)=interval from the beginning of the His-bundle spike to the end of rapid ventricular deflection in the HBE.

HBE was recorded at a paper speed of 500 mm $s^{-1}$ to calculate AV conduction intervals with 1.0-ms resolution (Visigraph 5L37, NEC San-ei, Ltd, Tokyo, Japan). Another 6F quadripolar electrode catheter was inserted into the right atrium via the right femoral vein for atrial pacing. An R-wave coupled cardiac stimulator (3F61, NEC San-ei, Instr., Ltd) delivering a rectangular monophasic pacing impulse of 1 ms duration was used for all atrial pacing. The stimulating current used was twice the threshold determined at the control state.

RR and PR intervals, QRS duration and QT interval were measured from ECG lead II. QT interval was corrected for heart rate by dividing the QT interval by the square root of the RR interval to obtain the QTc interval.[14]

AV conduction times measured in this study were as follows: A-H interval (AV nodal conduction time during sinus rhythm), St-H interval (intra-atrial and AV nodal conduction time during atrial pacing), H-V interval (His–Purkinje conduction time) and H-S interval (total ventricular conduction time). A-H interval was measured from the beginning of atrial deflection to the beginning of the His-bundle spike in the HBE.[15] The St-H interval was measured from the beginning of the stimulus artefact (St) to the beginning of the His-bundle spike in the HBE.[16] The H-V interval was measured from the beginning of the His-bundle spike to the beginning of ventricular deflection in the HBE.[15] The H-S interval was measured from the beginning of the His-bundle spike to the end of the rapid deflection in the HBE (fig. 1).[16]

## EXPERIMENTAL PROCEDURE

At the end of the surgical procedure, nitrous oxide was discontinued and the end-tidal concentration of sevoflurane was adjusted to 2.4% (1 MAC) and maintained for at least 20 min. After haemodynamic stabilization, control values of the variables mentioned above were obtained during both sinus rhythm and subsequent atrial pacing. The right atrium was paced constantly at 86 (7) beat $min^{-1}$ (paced cycle length of 708.6 (65.6) ms), which was slightly higher than control sinus rate during each administration of magnesium sulphate ($MgSO_4$). Twenty beats were recorded during sinus rhythm, and then the right atrium was paced for 1 min and 20 consecutive beats were recorded. Sinus rhythm returned immediately after pacing was discontinued.

All dogs were given a 10% solution of $MgSO_4$ in a bolus of 30, 60 and 90 mg kg$^{-1}$ at 15-min intervals. All measurements and blood sampling were performed 1–2 min after each administration of $MgSO_4$ during both sinus rhythm and subsequent atrial pacing.

### STATISTICAL ANALYSIS

Statistical analysis was performed using analysis of variance with repeated measures, followed by Fisher's protected least significant difference (PLSD). $P<0.05$ was considered statistically significant. Data are given as mean (SEM).

## Results

### CHANGES IN BLOOD ELECTROLYTE CONCENTRATIONS (TABLE 1)

Plasma total magnesium concentrations increased significantly from a control value of 1.3 (0.1) to 4.1 (0.3), 8.0 (0.8) and 15.3 (1.3) mg dl$^{-1}$ after $MgSO_4$ 30, 60 and 90 mg kg$^{-1}$, respectively. Plasma total calcium concentrations increased significantly at doses of $MgSO_4$ ≥30 mg kg$^{-1}$ ($P<0.05$) with no changes in serum $Ca^{2+}$ concentrations. Serum $K^+$ concentrations remained within the normal range.

### HAEMODYNAMIC EFFECTS (TABLE 2)

SAP, DAP, MAP and HR decreased significantly at doses ≥30 mg kg$^{-1}$ in a dose-related manner ($P<0.05$). Atrial pacing produced significant increases in SAP, DAP and MAP compared with each corresponding value obtained during sinus rhythm at 90, 30 and 30 mg kg$^{-1}$, respectively.

### ELECTROPHYSIOLOGICAL EFFECTS (TABLE 3)

$MgSO_4$ significantly prolonged A-H and St-H intervals at doses ≥30 mg kg$^{-1}$; H-V interval at doses ≥60 mg kg$^{-1}$ and H-S interval at doses ≥30 mg kg$^{-1}$ in a dose-related manner during both sinus rhythm and atrial pacing. There were no significant differences in AV conduction times between those obtained during sinus rhythm and atrial pacing. Atrial pacing rate was 86 (7) beat min$^{-1}$ (paced cycle length of 708.6 (65.6) ms), slightly greater than the control rate at sinus rhythm (82 (7) beat min$^{-1}$).

### ELECTROCARDIOGRAPHIC EFFECTS (TABLE 4)

RR and PR intervals were prolonged significantly at doses ≥30 mg kg$^{-1}$ during sinus rhythm. Significant differences were found in RR intervals between those obtained during sinus rhythm and atrial pacing at each dose of $MgSO_4$. QRS duration was prolonged significantly at doses ≥30 mg kg$^{-1}$ during sinus rhythm and at doses ≥60 mg kg$^{-1}$ during atrial pacing. The QT interval was prolonged significantly at doses ≥30 mg kg$^{-1}$ during both sinus rhythm and atrial pacing. The QTc interval remained unchanged during sinus rhythm and was significantly prolonged

*Table 1* Changes in blood electrolyte concentrations before and immediately after administration of magnesium sulphate (Mg $SO_4$) (mean (SEM)). Mg=Plasma total magnesium concentration; Ca=plasma total calcium concentration; $Ca^{2+}$=serum ionized calcium concentration; $K^+$=serum potassium concentration. Concentrations of Mg (mmol litre$^{-1}$) were calculated from the measured plasma concentrations of Mg (mg dl$^{-1}$). at doses ≥30 mg $kg^{-1}$ during atrial pacing. No changes in ST segment or T wave were observed and detrimental AV conduction block and arrhythmias did not occur at any dose of $MgSO_4$ throughout the study.

## Discussion

Magnesium sulphate 30, 60 and 90 mg $kg^{-1}$ i.v. produced acute hypermagnesaemia with 4–12-fold increases in plasma total magnesium concentrations compared with control values. Magnesium sulphate significantly decreased heart rate and prolonged cardiac conduction times and electrocardiographic variables, except for QTc interval during sinus rhythm, with 1 MAC of sevoflurane anaesthesia. Arterial pressures decreased in a dose-dependent manner.

A decrease in heart rate and prolongation of A-H interval caused by magnesium sulphate are consistent with results of previous studies *in vitro*[17] and *in vivo*.[18] It has been shown that $Mg^{2+}$ is a naturally occurring $Ca^{2+}$ antagonist[19 20] which reduces movement of extracellular $Ca^{2+}$ into the myocardial cell by a competitive process localized at the sarcolemmal membrane.[21] In addition, intracellular $Mg^{2+}$ has been shown to block outward movement of $K^+$ through potassium channels.[22] Therefore, the negative chronotropic and dromotropic effects of magnesium can be attributed to its blocking effects on calcium and potassium currents involved in the genesis of the action potential in sinoatrial[23] and atrioventricular (AV) node cells.[24]

In this study, A-H and H-V intervals were prolonged almost in parallel with increases in doses of $MgSO_4$ during sinus rhythm. This finding is consistent with previous results obtained in an isolated canine heart by Molter and colleagues.[25] In their study, both A-H and H-V intervals increased significantly at serum magnesium concentrations up to 6 mmol $litre^{-1}$, although the magnitude of this effect was greater for A-H interval. A serum $Mg^{2+}$ concentration of 6 mmol $litre^{-1}$ corresponds to a peak mean value of serum total magnesium concentration of 15.3 mg $dl^{-1}$, measured after $MgSO_4$ 90 mg $kg^{-1}$ in this study. Although actual serum $Mg^{2+}$ concentrations 1–2 min after bolus administration of each dose of $MgSO_4$ were unclear, these results suggest that both AV node cells and Purkinje fibres may be equally sensitive to the depressant effects of $Mg^{2+}$. In humans, however, magnesium has been shown not to affect H-V conduction.[11,12] These differences may be attributed to low peak serum magnesium concentrations in their study.

$Mg^{2+}$ has been shown to reduce conduction velocity of cardiac cells via a decrease in maximum upstroke velocity by blocking the Na channel,[17,26] although the relation between upstroke velocity and conduction velocity may not be as direct as has been thought.[27] Because Purkinje fibres and ventricular muscle have almost the same ionic mechanisms for development of an action potential, with conduction velocities dependent on the rate of rise of depolarization carried by the fast inward $Na^+$ current, significant prolongation of H-V and H-S intervals during both sinus rhythm and atrial pacing may be explained by the $Na^+$ current blocking action of $Mg^{2+}$.

Prolongation of A-H and H-S intervals during both sinus rhythm and atrial pacing is thought to be responsible for electrocardiographic prolongation of P-R intervals during sinus rhythm and QRS duration during both sinus rhythm and atrial pacing, respectively.

QT interval reflects the average action potential duration (APD) of ventricular muscle and is determined mainly by the balance between outward $I_k$ and inward $I_{Ca}$ during ventricular repolarization.[28] Because QTc interval remained unchanged in this study, significant prolongation of QT interval during sinus rhythm can be attributed to dose-related decreases in heart rate. Although the precise mechanism for the effects of $Mg^{2+}$ on APD is unclear, this study suggested that calculated external $Mg^{2+}$ in the range 1.7 to 6.3 mmol litre$^{-1}$ did not affect the balance between outward $I_k$ and inward $I_{Ca}$ during repolarization with sevoflurane anaesthesia. While significant prolongation of QTc interval during atrial pacing may be attributed to decreases in R-R intervals induced with higher pacing rates than sinus rates, it is noteworthy that QT interval remained significantly prolonged during atrial pacing, as seen during sinus rhythm. A possible mechanism for this effect of $Mg^{2+}$ could be explained by impairment of an intracellular calcium-induced $I_{Ca}$ inactivation process.[29,30] Because $Mg^{2+}$ decreases $I_{Ca}$ through open channels during depolarization,[31,32] the increasing rates of ventricular depolarization induced with atrial pacing might not be accompanied by a sufficient increase in intracellular $Ca^{2+}$ concentration to activate the calcium-induced $I_{Ca}$ inactivation process and subsequently to shorten the plateau phase of APD, that is QT interval.

In this study, atrial pacing was performed to exclude the effects of heart rate on AV conduction times. The fact that the St-H interval was 30-40 ms longer than the A-H interval during sinus rhythm probably reflects the latency between stimulus and atrial activation. Because incremental increases in atrial-paced rates were not performed in this study, the effects of magnesium on the rate-dependence of AV nodal conduction times during sevoflurane anaesthesia were unclear.

The electrophysiological and electrocardiographic effects of sevoflurane have not been fully studied. Although autonomic system activity might be depressed to some extent by sevoflurane, 1 and 2 MAC of sevoflurane exerted no significant effects on heart rate or cardiac conduction times in pentobarbitone-anaesthetized dogs in our previous study.[8] Therefore, the direct effects of magnesium on the cardiac conduction system could predominate over the effect of sevoflurane on this system. Hatakeyama, Ito and Momose[33] reported that sevoflurane depressed overshoot and the upstroke velocity, and the plateau phase of action potentials at higher concentrations (>2.0%) without affecting resting membrane potential. These findings suggest that the electrophysiological interaction between sevoflurane and $Mg^{2+}$ may occur additively or synergistically through blocking actions on transmembrane $Na^+$ and $Ca^{2+}$ influx. It is not known if the electrophysiological effects of $MgSO_4$ are enhanced at higher concentrations than 1.0 MAC of sevoflurane.

To clarify the possible clinical electrophysiological risk of magnesium during sevoflurane anaesthesia, a battery of electrophysiological tests, including measurements of sinus node recovery time, AV nodal refractory periods and Wenckebach cycle length should be performed with lower (0 and 0.5 MAC) or higher (1.5 MAC and above) concentrations of sevoflurane. Although there were several limitations to our study mentioned above, our results suggest that magnesium should not exert adverse effects on AV conduction times during 1.0 MAC of sevoflurane anaesthesia.

In conclusion, serum concentrations of magnesium up to 15.3 mg dl$^{-1}$ did not produce detrimental electrophysiological or electrocardiographic effects in the presence of 1 MAC of sevoflurane. To apply these findings to clinical anaesthesia, however, further studies should be performed to examine the interaction between magnesium and anaesthetics for potential adverse effects that may occur on the electrophysiology of the heart.

# Prolonged peribulbar anaesthesia with indwelling catheter: a preliminary report of 217 cases†

J.-M. BERNARD AND J.-L. HOMMERIL

## Summary

We report a technique to prolong peribulbar anaesthesia by repetitive injections of lignocaine through a catheter in the inferotemporal peribulbar space during surgery anticipated to exceed 60 min. After peribulbar anaesthesia by standard percutaneous approach with the eye looking straight, a 19-gauge Tuohy needle was inserted backwards in the sagittal plane and parallel to the 5° slope of the orbit floor, to a distance of less than 3 cm, at the junction of the middle and lateral third of the lower orbital rim. A 23-gauge smooth catheter was advanced up to the tip of the needle which was withdrawn, keeping less than 3 cm of catheter in the inferotemporal compartment. A catheter was inserted in 217 consecutive patients undergoing vitrectomy, retinal detachment and retinal peeling. There were no technical difficulties. Neither additional sedation nor general anaesthesia was required during surgery, but less than 50% of patients requested lignocaine injections to supplement anaesthesia. Catheter insertion into the peribulbar space may represent a potential technique to perform a greater variety of ophthalmic surgery with regional anaesthesia. Indications should be limited to the longest procedures. (*Br. J. Anaesth.* 1997; **78**: 81–82)

**Key word**
Anaesthetic techniques, regional, peribulbar. Surgery, ophthalmological. Equipment, catheters.

Retrobulbar block has been used widely for various types of ophthalmic surgery; it consists of injection of a small volume of local anaesthetic into the extraocular muscle cone to anaesthetize the ciliary ganglion and nerves innervating the rectus muscles. However, as this technique involves blind insertion of a needle into a space occupied by delicate neural and vascular structures, complications can occur. With peribulbar injection, a larger volume of anaesthetic is injected with no attempt to enter the muscle cone which, at least theoretically, is less dangerous.[1 2] With time, the anaesthetic agent diffuses and adequate anaesthesia is obtained.

However, peribulbar block may be inadequate for prolonged procedures, such as posterior segment surgery. We describe a technique to prolong peribulbar anaesthesia by repetitive injections through a catheter in the inferotemporal peribulbar space.

## Methods and results

After local Institutional Human Investigation Committee review, we studied 217 consecutive ASA I–III patients undergoing ophthalmic surgery which was anticipated to exceed 60 min. During the preoperative visit, this aspect of anaesthetic management was explained and informed consent was obtained. Patients with impaired haemostasis or receiving oral anticoagulants and those with previous ipsilateral eye surgery were excluded. No premedication was given.

Peribulbar anaesthesia was produced initially by a standard percutaneous approach with the eye looking straight. Using a 27-gauge, 31-mm disposable retrobulbar needle, 5–8 ml of a 0.5% bupivacaine and 2% lignocaine mixture in equal proportion were injected into the inferotemporal compartment, followed 2 min later by a second injection for medial compartment peribulbar block. A bolus of propofol 0.5–1 mg $kg^{-1}$ i.v. was given to lessen the discomfort and awareness of the injection. Peribulbar block and consequently a peribulbar catheter technique should also be achievable after local anaesthesia of the inferotemporal conjunctival fornix, avoiding the need for propofol and preserving the advantages of local anaesthesia in very old and fragile patients.[3] Continuous decompression using a Honan balloon at a setting of 30 mm Hg was applied while patients recovered from propofol sedation.

Patients were asked to move their eyes, using maximal effort in the superior, inferior, medial and lateral directions. If globe akinesia was incomplete, a supplementary injection was given. When akinesia was complete, a 19-gauge Tuohy needle (Paediatric Extradural Set System 2, Rüsch Laboratory) was inserted under sterile conditions. The needle entry

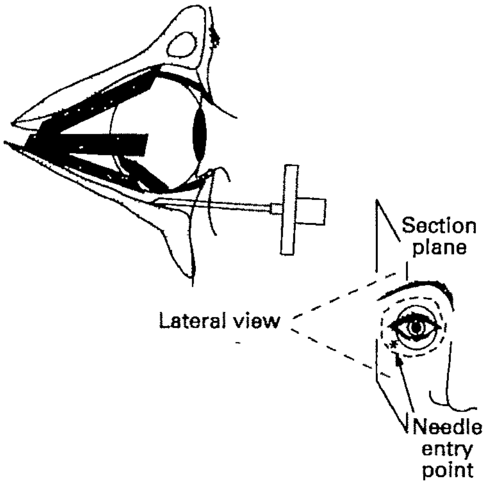

*Figure 1* Schematic drawing of the orbit after vertical section. Placement of the Tuohy needle as seen from the lateral view. The tip of the needle passed backwards in the sagittal plane and parallel to the 5° upward slope of the orbital floor. We recommend that a Tuohy needle with clear guide marks is used to avoid a depth greater than 3 cm from the orbital rim. *Needle entry point; inferotemporal approach at the junction of the middle and lateral third of the inferior orbital rim (broken line).

point was the junction of the middle and lateral third of the inferior orbital rim. Based on anatomical knowledge, the needle tip passed transcutaneous, backwards in the sagittal plane, parallel to the 5° upward slope of the orbit floor, less than 3 cm from the orbital rim (fig. 1). The initial peribulbar block probably pushed tissue and the eye away from the Tuohy needle, reducing the risk of penetration into the cone and into the globe. A 23-gauge smooth catheter was introduced and advanced up to the tip of the needle which was withdrawn, keeping less than 3 cm of catheter in the peribulbar space. In contrast with previously described techniques,[4–6] we avoided an upward and medial direction of the Tuohy needle which may result in retrobulbar placement with an increased risk of optic nerve injury, globe perforation and haemorrhage or, because of a possible retrobulbar position of the catheter after withdrawal of the needle, may be accompanied by serious central nervous system complications at the time of drug administration.[2]

Continuous decompression was then performed until surgery started. The catheter was taped to the cheek with plaster. During surgery, patients received a 5-ml bolus of 2% lignocaine via the catheter at each complaint of pain. After negative test aspiration, each injection was made slowly, over 2 min, to avoid significant increased pressure in the operating field. Injection was discontinued if the surgeon requested it, to be completed later. During the entire procedure, we monitored continuously heart rate and pulse oxygen saturation. Arterial pressure was measured by automated sphygmomanometry. After leaving the operating theatre, patients were asked to evaluate the quality of anaesthesia using a five-point scale.

Mean age and weight of the patients were 64 (range 16–89) yr and 66 (SD 13) kg, respectively. Time of decompression was 32 (SD 11) min. A catheter was used for prolonging anaesthesia in 92 patients, most often for one injection (58 cases). Three patients required up to four injections of lignocaine, thus receiving a maximum dose of 560 mg, including the initial block. The time for the first request from the initial peribulbar block was 52 (15) min, with wide inter-individual variability (range 25–95 min). Surgery included 28 cases of vitrectomy (duration 43 (range 15–80) min), 121 cases of retinal detachment (duration 56 (10–120) min) and 68 cases of retinal peeling (duration 33 (15–60) min). Use of the catheter was, respectively, 54%, 52% and 20%.

## Comment

Verbal contact was maintained in all patients. Neither additional sedation nor general anaesthesia was required. Intraoperative injection of lignocaine 5 ml was compatible with continuation of surgery and did not inconvenience the surgeon. With the exception of one patient who declared that the operation was unpleasant, there were no bad or medium responses when we asked patients to evaluate anaesthesia. No local complications were observed, except two cases of lower eyelid haematoma which resolved spontaneously. No symptoms of local anaesthetic toxicity were observed. One episode of reflex bradycardia (heart rate less than 40 beat $\text{min}^{-1}$) was observed in a 40-yr-old patient who had received three injections of lignocaine for inadequate analgesia. With the exception of this case, there were no changes in heart rate, arterial pressure or pulse oxygen saturation during surgery.

We conclude that catheter insertion into the peribulbar space is an easy and reliable method of performing a greater variety of ophthalmic surgery with regional anaesthesia.

# Continuous brachial plexus infusion of butorphanol–mepivacaine mixtures for analgesia after upper extremity surgery

Z. WAJIMA, T. SHITARA, Y. NAKAJIMA, C. KIM, N. KOBAYASHI, H. KADOTANI, H. ADACHI, G. ISHIKAWA, K. KANEKO, T. INOUE AND R. OGAWA

## Summary

We have recently reported that continuous administration of butorphanol into the brachial plexus neurovascular sheath provided superior analgesia compared with that obtained with continuous i.v. administration. Furthermore, we found that analgesia was most pronounced when a mixture of mepivacaine and butorphanol was given and that butorphanol alone ranked next. In this study, we increased the dose of butorphanol, compared with that used in our previous reports, and an initial bolus dose of butorphanol was administered into the brachial plexus neurovascular sheath just after surgery had ended. Thereafter, postoperative pain relief was estimated. In patients undergoing upper extremity surgery with continuous axillary brachial plexus block, group A received a bolus of 1 ml of physiological saline with 1.5% mepivacaine, 10 ml into the brachial plexus sheath followed by a continuous brachial plexus infusion of 0.5% mepivacaine with butorphanol 6 mg at a rate of 144 ml/72 h. Group B was given a bolus of butorphanol 1 mg (1 ml) with 1.5% mepivacaine, 10 ml into the brachial plexus sheath and a continuous brachial plexus infusion of 0.5% mepivacaine with butorphanol 6 mg at a rate of 144 ml/72 h. After operation, VAS scores did not differ between the two groups. The time to first use of supplementary analgesia did not differ significantly between the groups and there were no significant differences in the number of patients who required supplementary analgesia. These results indicate that continuous butorphanol 2 mg day$^{-1}$ with 0.5% mepivacaine provided sufficient postoperative analgesia after upper limb surgery. (*Br. J. Anaesth.* 1997; **78**: 83–85)

**Key words**
Analgesia, postoperative. Analgesic techniques, regional, brachial plexus. Analgesics opioid, butorphanol. Anaesthetics local, mepivacaine.

We reported recently that administration of analgesics into the brachial plexus neurovascular sheath produced good postoperative analgesia after upper limb surgery[1 2]: we showed that continuous administration of butorphanol into the brachial plexus neurovascular sheath provided superior analgesia compared with that achieved with continuous systemic i.v. injection after upper extremity surgery.[1] Furthermore, we compared postoperative pain relief produced by continuous infusion of three types of solution into the axillary sheath (butorphanol alone, mepivacaine alone or a mixture of mepivacaine and butorphanol) and found that analgesia was most pronounced with a mixture of mepivacaine and butorphanol and that butorphanol alone ranked next.[2] We proposed that it might be possible to potentiate postoperative pain relief by increasing the concentration of local anaesthetic, increasing the rate of administration of local anaesthetic or increasing the dose of opioid.[2] In this study, we increased the dose of butorphanol, compared with our previous reports,[2] and estimated postoperative pain relief after initial bolus administration of butorphanol into the brachial plexus neurovascular sheath just after surgery had ended.

## Methods and results

With the approval of our institutional Ethics Committee and written informed consent, we studied 25 patients undergoing elective upper extremity surgery. All patients were ASA I or II, aged 13–82 yr. Similar surgical procedures were performed in both groups. Surgery was performed by the same orthopaedic surgeon. Patients received oral roxatidine acetate hydrochloride ($H_2$ antagonist) 75 mg, on the night before surgery and 2 h before entering the operating room.

During surgery, patients were given a continuous axillary brachial plexus block by i.v. administration of 30 ml of 1.5% mepivacaine after repeated aspiration tests. The block was performed as previously.[1 2] All blocks were performed by the same anaesthetist.

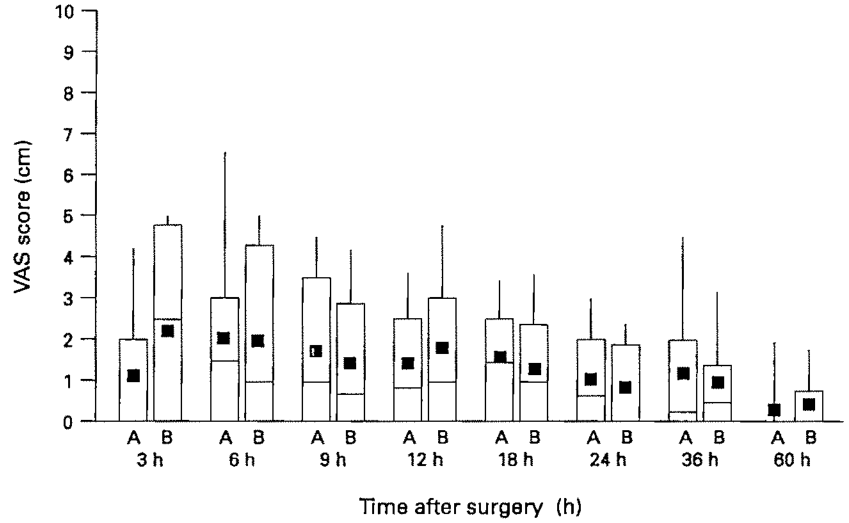

*Figure 1* Postoperative visual analogue scale (VAS) scores in groups A and B. Lower and upper borders of the box=25th to 75th percentiles; horizontal line within the box=median, marking the 50th percentile; rectangular symbols in the box=mean; and error bars=90th percentile.

*Table 1* Number of patients requiring supplementary analgesia and those showing side effects after surgery. No significant differences between the groups

| | Group A ($n$=14) | Group B ($n$=11) |
|---|---|---|
| Required supplementary analgesia | 5 | 4 |
| Nausea | 3 | 5 |
| Vomiting | 2 | 4 |
| Slight drowsiness | 3 | 4 |
| Dizziness | 1 | 2 |

Surgery was started after complete analgesia was obtained in the surgical field. Mepivacaine 1.5% (10 ml) was given every 90 min. Sedation was provided by midazolam i.v. at the discretion of the anaesthetist. Patients were excluded from the study when complete analgesia in the surgical area was not achieved with the initial block.

Immediately after surgery had ended, patients were allocated randomly, in a double-blind design, to one of two groups. Group A received a bolus of 1 ml of physiological saline with 1.5% mepivacaine, 10 ml into the brachial plexus sheath followed by continuous brachial plexus infusion of 0.5% mepivacaine with butorphanol 6 mg at a rate of 144 ml/72 h using a disposable-type continuous microinfuser (Infusor LV2ml/hr, Baxter Healthcare Corporation, Deerfield, IL, USA). The solution consisted of 1% mepivacaine 72 ml, physiological saline 66 ml and butorphanol 6 ml (6 mg). Group B was given a bolus of butorphanol 1 mg (1 ml) with 1.5% mepivacaine, 10 ml into the brachial plexus sheath followed by continuous brachial plexus infusion of 0.5% mepivacaine with butorphanol 6 mg at a rate of 144 ml/72 h.

Diclofenac sodium suppository was available for supplementary analgesia to establish comfort at rest; this was administered as a single 50-mg dose. No other opioids or sedatives were administered.

Patients rated pain at rest on 10-cm unmarked linear visual analogue scales, ranging from "no pain" to "unbearable pain". Scores were recorded at 3, 6, 9, 12, 18, 24, 36 and 60 h after surgery. The time and dose of supplementary analgesic medication were recorded.

There were 14 patients assigned to group A and 11 to group B. There were no significant differences between the two groups in sex distribution, age, weight, height, dose of 1.5% mepivacaine or duration of surgery (Fisher's exact probability tests, unpaired $t$ test and Mann–Whitney $U$ test).

Postoperative VAS scores did not differ between the two groups (fig. 1).

The time to first use of supplementary analgesia (diclofenac sodium suppository) did not differ significantly between the two groups using survival analysis (generalized Wilcoxon test and Cox–Mantel test), and there were no significant differences between the groups in the numbers of patients who required supplementary analgesia (table 1). There were no significant differences in the incidence of side effects between the two groups (table 1).

## Comment

Extradural analgesia with combinations of local anaesthetics and opioids is commonly used for postoperative pain relief[3] and initial bolus administration of opioid or local anaesthetic, or both, is generally conducted before continuous infusion of analgesics.[4] In our recent report,[2] we suggested that postoperative pain relief might be potentiated by increasing the concentration of local anaesthetic, increasing the rate of administration of local anaesthetic or increasing the dose of opioid. In this study, we increased the dose of butorphanol, compared with that used previously,[2] by administering an initial bolus dose of butorphanol into the brachial plexus sheath just after surgery had ended. Thereafter, postoperative pain relief was estimated.

There were no significant differences between the groups in VAS scores, time to first use of supplementary analgesia and number of patients who required supplementary analgesia, implying that continuous butorphanol 2 mg day$^{-1}$ was sufficient for postoperative analgesia after upper limb surgery. The reason for the lack of difference between the two groups in postoperative pain scores was that both pain relief methods were probably adequate for postoperative pain relief from the early postoperative period. To potentiate postoperative pain relief, we recommend increasing the concentration of local anaesthetic or increasing the rate of administration of local anaesthetic, especially during the early postoperative period.

Peripherally acting opioids[5 6] are likely to be useful clinically because the reduction in adverse effects by the use of low-dose opioids would be advantageous, but further investigation is needed.

# Validation of pulse oximetry for monitoring of hypoxaemic episodes in the late postoperative period

K. STAUSHOLM, S. ROSENBERG-ADAMSEN, L. EDVARDSEN, H. KEHLET AND J. ROSENBERG

## Summary

We monitored 12 patients undergoing major abdominal surgery using a pulse oximeter (Nellcor N-200) and a transcutaneous oxygen tension monitor (TINA, Radiometer A/S) on the second or third night after operation. Of the shortest hypoxaemic episodes measured with the pulse oximeter ($\leq$30 s duration), 78% also occurred in the transcutaneous oxygen tension measurement. Episodes of longer duration ($\geq$1 min duration on the pulse oximeter) were, in 95% of cases, reflected in the transcutaneous oxygen tension measurement also. Thus postoperative episodic desaturations lasting $\geq$1 min are at least 95% likely to be a real phenomenon. (*Br. J. Anaesth.* 1997; **78**: 86–87)

**Key words**
Oxygen, inspired concentration. Oxygen saturation. Hypoxaemia. Measurement techniques, oximeters. Surgery, postoperative period.

Late postoperative episodic hypoxaemia is frequent during the second to fourth nights after major surgery, and may be related to development of cardiac complications.[1] Postoperative episodic hypoxaemia has been verified previously by pulse oximetry. However, it is possible that some of the hypoxaemic episodes may have been motion artefacts rather than hypoxaemic events.[2] Measurement of transcutaneous oxygen tension using a heated Clark electrode is not sensitive to motion,[3] and this method is therefore a suitable reference for validating pulse oximetry monitoring of episodic hypoxaemia.[4]

The aim of the study was to validate pulse oximetry for monitoring of episodic hypoxaemia after major surgery by simultaneous and continuous monitoring of transcutaneous oxygen tension ($Tc_{O_2}$) and transcutaneous oxygen saturation ($Sp_{O_2}$).

## Methods and results

We studied 12 patients (six men, median age 66 (range 44–84) yr, weight 70 (55–85) kg, height 170 (160–180) cm) in the ward after major abdominal surgery. Patients were studied on the second or third night after laparotomy during the hours of 23:00–07:00. Eight patients underwent colonic resection, two gastric procedures and two operations for adhesions. The anaesthetic technique was inhalation (enflurane, 11 patients) or i.v. (midazolam/low-dose fentanyl, one patient). Nine of the patients received additional extradural anaesthesia during operation. Supplementary oxygen therapy was not given during the study night. In nine patients postoperative pain therapy was performed with continuous extradural infusion of bupivacaine 10 mg $h^{-1}$ and morphine 4.8 mg $day^{-1}$, and in three patients postoperative pain was treated with morphine i.m. on demand.

Arterial oxygen saturation ($Sp_{O_2}$) was measured continuously with a Nellcor N-200 pulse oximeter (Nellcor Inc., Pleasanton, CA, USA) using an adhesive finger probe, and transcutaneous oxygen tension ($Tc_{O_2}$) was measured with a TINA transcutaneous oxygen tension monitor (Radiometer A/S, Copenhagen, Denmark). The $Tc_{O_2}$ electrode was heated to 43 °C and placed distally at the volar side of the same arm as the $Sp_{O_2}$ probe. Data for $Sp_{O_2}$ and $Tc_{O_2}$ were printed simultaneously at bedside on an analogue recorder.

An episodic hypoxaemic event in the $Sp_{O_2}$ tracing was defined as a sudden reduction in $Sp_{O_2}$ of $\geq$5% from baseline and occurring within 2 min.[1] In the $Tc_{O_2}$ tracing a hypoxaemic event was defined as a sudden reduction in $Tc_{O_2}$ of more than 0.3 kPa and occurring within 2 min. Events were considered to be coherent if the $Tc_{O_2}$ event was delayed by not more than 30 s from the $Sp_{O_2}$ event.

The study was approved by the local Ethics Committee and all patients gave written informed consent. Group data are given as median (range). For statistical analyses we used Fisher's exact test. $P<0.05$ was considered statistically significant.

Duration of surgery was 175 (75–290) min. For the group of 12 patients, median $Sp_{O_2}$ was 93 (91–96) % and $Tc_{O_2}$ was 4.3 (3.8–5.9) kPa. A total of 481 hypoxaemic episodes were recorded on the pulse oximeter (table 1), of which 424 (88%) episodes were transmitted to the $Tc_{O_2}$ tracing. There were no instances of episodes in the $Tc_{O_2}$ curve not reflected in the $Sp_{O_2}$ curve; 95% of the hypoxaemic

episodes lasting ≥1 min also occurred on the $Tc_{O_2}$ curve, whereas 5% did not (difference between rates=90%, 95% confidence limits of difference between rates=78–101%).

## Comment

The principal finding of our study was that episodic oxygen desaturations were reflected in transcutaneous oxygen tension measurements in 95% of cases if the episodes lasted 1 min or more. It is presumed that if a hypoxaemic episode occurs in both $Sp_{O_2}$ and $Tc_{O_2}$ tracings it is "real", and if it occurs only in the $Sp_{O_2}$ curve it may (or may not) be an artefact. Thus at least 95% of episodes lasting ≥1 min were real.

Pulse oximetry needs arterial pulsation to measure oxygen saturation. Thus in circumstances when decreased pulsation occurs, for example hypothermia, hypotension and vasoconstriction decrease the ability of the oximeter to measure arterial oxygen saturation. It is not likely, however, that this was the case for the shorter lasting episodes in this study. Movement artefacts may be a significant source of error in pulse oximetry measurements.[2] A previous study evaluating four oximeters in an experimental setting with vibration found no false hypoxaemic episodes with the Nellcor N-200 oximeter (when the $Sp_{O_2}$ signal was read in conjunction with the ECG signal for data verification) whereas the Ohmeda 3700, the Simed S100 and the Datex Satlite Plus reported spurious hypoxaemic episodes, that is movement artefacts.[2]

The relationship between transcutaneous and arterial oxygen tension depends on skin temperature, skin thickness, chosen place for measurement and correct preparation of the skin.[5] Measurement of transcutaneous oxygen tension, however, is not dependent on motion.[3] In adults, values for transcutaneous oxygen tension are normally much lower than arterial values.[3] Thus in our study the median $Tc_{O_2}$ was only 4.3 kPa. This method is therefore not suitable for measuring exact values for arterial oxygen tension, but sudden changes in arterial oxygen tension are reflected in transcutaneous measurements.[3 4] However, there is the question of response time for the $Tc_{O_2}$ technique. Previous studies have found that with acute changes in arterial oxygen tension, the $Tc_{O_2}$ signal may be dampened or delayed because of the time for transport of oxygen through the skin.[5] Based on various assumptions and the results of earlier experimental studies, this transport time has been estimated to be in the order of 30 s.[5] In our study, when examining the actual curves for $Sp_{O_2}$ and $Tc_{O_2}$, changes resembled more of an "all or nothing" phenomenon; either the $Sp_{O_2}$ event was reflected almost simultaneously in the $Tc_{O_2}$ curve or the $Sp_{O_2}$ event did not occur. Our limit of 30 s between the $Sp_{O_2}$ and $Tc_{O_2}$ events was arbitrary, as no episodes were reflected in the $Tc_{O_2}$ curve with a delay of more than 30 s. It is therefore more likely that the discrepancy between some of the shortest $Sp_{O_2}$ events and the $Tc_{O_2}$ tracing was caused by motion artefacts (thus an error in the $Sp_{O_2}$ measurement), rather than the $Tc_{O_2}$ not reporting actual hypoxaemic events.

In summary, $Sp_{O_2}$ desaturations lasting ≥1 min, assessed using pulse oximetry in the late postoperative period, represented, with at least 95% certainty, an actual hypoxaemic episode. Short-lasting (≤30 s) episodic hypoxaemia, as assessed by pulse oximetry, may in 22% of instances or less, not reflect an actual hypoxaemic event.

# Spinal anaesthesia inhibits central temporal summation

M. CURATOLO, S. PETERSEN-FELIX, L. ARENDT-NIELSEN AND A. M. ZBINDEN

## Summary

In a previous investigation we found that extradural anaesthesia did not adequately inhibit temporal summation of repeated electrical stimuli: pain to repeated stimuli was blocked in only one of 10 patients, and pain thresholds to repeated stimuli were significantly lower than pain thresholds to a single stimulus. In this study we have investigated in 10 patients the effect of spinal anaesthesia on temporal summation, assessed by repeated electrical stimulation of the sural nerve. Plain 0.5% bupivacaine 18 mg was injected at L2–3. The pain threshold to a single electrical stimulus, summation threshold (increase in perception during repeated electrical stimuli with five impulses of the same intensity at 2 Hz), pinprick and cold sensation were assessed. After spinal anaesthesia, pain to both single and repeated stimulation, and pinprick and cold sensation, disappeared in all patients. We conclude that spinal anaesthesia inhibits temporal summation elicited by repeated electrical stimulation. (*Br. J. Anaesth.* 1997; **78**: 88–89)

**Key words**
Anaesthetic techniques, subarachnoid. Pain, experimental. Pain, threshold.

Repetition of a peripheral stimulus can cause increased pain perception (temporal summation). Increased and prolonged firing of dorsal horn neurones after repeated stimulation[1] (central sensitization) is probably the mechanism explaining temporal summation.

Repeated cutaneous stimulation can be used to investigate temporal summation in humans.[2] Nociceptive reflex and subjective pain thresholds after repeated stimulation have been found to be increased slightly by isoflurane concentrations used for surgical analgesia,[3] ketamine[4] and alfentanil,[5] although none of these drugs adequately blocked temporal summation. In a previous investigation,[6] we found that even extradural anaesthesia did not completely block temporal summation of repeated electrical stimuli: pain to repeated stimuli was blocked in only one of 10 patients, and pain thresholds to repeated stimuli were significantly lower than pain thresholds to a single stimulus.

The aim of this study was to assess the effect of spinal anaesthesia on temporal summation, assessed by repeated electrical stimulation.

## Methods and results

We studied 10 ASA I–II patients (five male), median age 43 (range 18–54) yr, median body weight 71 (54–85) kg and median height 170 (157–182) cm, undergoing spinal anaesthesia for elective surgery. Exclusion criteria were: age less than 18 or more than 65 yr, heart disease, pregnancy, opioid intake during the last 2 weeks, intake of other analgesics during the last 24 h, alcohol abuse and use of psychotropic drugs. The study was approved by the local Ethics Committee and informed consent was obtained from all patients.

Patients were not premedicated. Spinal anaesthesia was performed in the sitting position, at L2–3, with a 27-gauge Quincke needle, by the midline approach. Plain 0.5% bupivacaine 18 mg was injected over 40–45 s, with the bevel of the needle pointing cranially. Cerebrospinal fluid (0.2 ml) was aspirated and re-injected after administering half and the whole dose, to assure intrathecal placement of the needle. After injection patients were placed in the supine horizontal position.

Bipolar surface silver–silver chloride electrodes were placed behind the lateral malleolus for stimulation of the sural nerve. A 25-ms, train-of-five, 1-ms, square-wave impulse (perceived as a single stimulus) was delivered from a computer-controlled constant current stimulator (University of Aalborg, Denmark). To determine the single stimulus pain threshold, current intensity was increased from 2 mA in steps of 1–5 mA until pain was evoked, or a maximum current of 60 mA was reached. In the last case, the threshold was defined as 60 mA. The mean of two threshold measurements was calculated. To determine the threshold for temporal summation, the single stimulus was repeated five times at 2 Hz.[2] Current intensity was increased as described above until summation (increase in perception during the five stimuli) was observed, or a maximum current of 60 mA was reached. In the last case, the threshold

*Table 1* Median values (ranges) of thresholds to single (pain threshold) and repeated (increasing perception during five stimulations at 2 Hz) electrical stimulation of the sural nerve. Number of patients displaying slight or normal perception of pinprick and cold at the site of electrical stimulation

| | Basal | 10 min | 20 min | 30 min | 40 min |
|---|---|---|---|---|---|
| Single stimulus threshold (mA) | 7 (2–12) | 60 (19–60) | 60 (39–60) | 60 (60–60) | 60 (60–60) |
| Repeated stimuli threshold (mA) | 4 (1–7) | 53 (10–60) | 60 (35–60) | 60 (40–60) | 60 (60–60) |
| Pinprick sensation (No. patients) | 10 | 1 | 0 | 0 | 0 |
| Cold (No. patients) | 10 | 0 | 0 | 0 | 0 |

was defined as 60 mA. The mean of two threshold measurements was calculated.

Sensitivity to pinprick and cold were tested 2 cm anterior to the site of electrical stimulation (dermatome S1) and on the forehead to allow comparison with a non-anaesthetized area. Pinprick was performed with a 21-gauge sharp-bevelled needle, and cold test with gel bags (Physiopack, Fisch Laboratories) kept in a freezer, applied to 4 cm$^2$ of skin surface for 2 s. Tests were considered positive when patients reported normal or light perception of puncture or cold compared with sensation at the forehead.

Before spinal puncture a test series (single and repeated stimulations of the sural nerve, pinprick and cold) was performed for training, followed by baseline recordings. The test series was then repeated 10, 20, 30 and 40 min after spinal injection. The upper and lower levels of sensory block were determined 40 min after injection by absence of pinprick sensation. At the end of the experiment patients were transported to the operating room for surgery.

The median upper level of sensory block, as assessed by pinprick, was T9 (range T3–L4). Block of S5 was achieved in every patient.

Each test series lasted 2–4 min. After anaesthesia all patients had single stimulus and summation thresholds more than 60 mA (table 1). Pain to repeated stimulation disappeared in all patients. All patients lost both pinprick and cold sensation.

## Comment

We have shown that spinal anaesthesia effectively blocked pain elicited by single and repeated electrical stimulations of the sural nerve. Pain could not be evoked in any of the 10 patients by repeated stimulation with a maximum current intensity of 60 mA. This contrasts our previous study,[6] where extradural anaesthesia blocked pain to repeated stimulations in only one of 10 patients.

Pinprick and cold sensation disappeared very rapidly after spinal anaesthesia, when pain could still be evoked by electrical stimulation (table 1). This confirms that pinprick and cold tests inadequately assess the efficacy of regional block.[6]

We conclude that spinal anaesthesia inhibits temporal summation of nociceptive stimuli elicited by repeated stimulation of the sural nerve. This indicates that spinal anaesthesia can prevent sensitization of dorsal horn neurones during nociceptive stimulation and could be useful for the prevention of hyperalgesic states.

# Neuromuscular effects of rocuronium in patients receiving beta-adrenoreceptor blocking, calcium entry blocking and anticonvulsant drugs

P. B. LOAN, F. M. CONNOLLY, R. K. MIRAKHUR, N. KUMAR AND P. FARLING

## Summary

We have studied the onset and duration of action of rocuronium 0.6 mg $kg^{-1}$ in patients receiving therapy for more than 1 month with beta-receptor blocking drugs ($n=16$), calcium entry blocking drugs ($n=17$) or anticonvulsant drugs ($n=14$) and compared these data with those from a control group ($n=27$). Anaesthesia comprised fentanyl, propofol infusion and nitrous oxide in oxygen. Neuromuscular block was monitored by measuring the force of contraction of the adductor pollicis muscle in response to train-of-four (TOF) stimulation. There were no significant differences in onset times between the four groups (mean 62–76 s). Mean times to 25% recovery of T1 (first response in the TOF) and of the TOF ratio of 0.7 were 38 (SD 15) and 58 (22) min, 36 (8) and 61 (19) min, 40 (11) and 68 (22) min, and 25 (6) and 35 (9) min in the control, beta-blocker, calcium entry blocker and anticonvulsant groups, respectively ($P<0.01$ between the anticonvulsant and other groups). We conclude that chronic therapy with anticonvulsant drugs reduces the duration of action of rocuronium. (*Br. J. Anaesth.* 1997; **78**: 90–91)

**Key words**
Neuromuscular block, rocuronium. Interactions (drug). Sympathetic nervous system, adrenergic block. Calcium channel block. Anticonvulsants

Rocuronium is a new non-depolarizing neuromuscular blocking agent with an intermediate duration of action, but with a rapid onset of action.[1] Previous experimental or clinical studies have shown significant alterations in the effects of neuromuscular blocking agents by anticonvulsant, beta-receptor antagonist and calcium channel blocking drugs or in those receiving chronic therapy with these agents.[2–4] Knowledge of these interactions may be important to enable the anaesthetist to avoid delays and risk to the patient from over-curarization, or to anticipate the need for more frequent dosing. The aim of this study was to investigate any clinically important effects of therapy with these three commonly prescribed groups of drugs on the onset and duration of action of rocuronium.

## Methods and results

We studied 74 ASA I–III patients, aged 18–74 yr, with their written informed consent and approval of the Research Ethics Committee. Sixteen patients were receiving chronic therapy (for at least 1 month) with beta-receptor blocking drugs (propranolol and atenolol five each, metoprolol and bisoprolol two each, oxprenolol and celiprolol one each), 17 with calcium entry blocking drugs (nifedipine 12, diltiazem and nicardipine two each, amlodipine one), and 14 with anticonvulsant drugs (carbamazepine alone or in combination with other anticonvulsants 12, phenytoin one, sodium valproate one). Twenty seven patients in the "control" group were not receiving any of these or any other drugs known to interact with neuromuscular blocking agents.

Patients were premedicated with temazepam 10–20 mg and anaesthetized with fentanyl 1–3 μg $kg^{-1}$, propofol 1–2.5 mg $kg^{-1}$ followed by an infusion of propofol, and 65% nitrous oxide in oxygen. The ulnar nerve was stimulated transcutaneously with supramaximal stimuli of 0.2 ms duration in a train-of-four (TOF) sequence at 2 Hz every 12 s and the resultant force of contraction of the adductor pollicis muscle was measured and recorded using a force transducer and a neuromuscular function analyser (Myograph 2000, Biometer Ltd, Denmark). Hand skin temperature was maintained above 32 °C.

The control responses were stabilized for approximately 10 min before administration of rocuronium 0.6 mg $kg^{-1}$. The times from administration of rocuronium to maximal depression of T1 (onset time) and its recovery to 25, 75 and 90% of control, and of recovery of the TOF ratio to 0.7, were recorded. Patient data were subjected to the Kruskal–Wallis test followed by Dunn's test, if significant differences were observed. Neuromuscular data between the control and each of the study groups were subjected to the Wilcoxon test using the Hochberg–Bonferroni correction. $P<0.05$ was accepted as significant.

The times to onset of maximum block and

recovery are shown in table 1. Onset times did not differ significantly between the groups. All patients attained 100% block. There were no significant differences in the recovery times between the control, beta-receptor blocker and calcium entry blocker groups. However, the times for recovery of T1 to 25% and of the TOF ratio to recover to 0.7 in the anticonvulsant group were significantly shorter compared with the other groups ($P<0.01$). The mean T1 25–75% recovery index of 9 min in this group, although shorter, was not statistically significant at the 5% level ($P=0.06$).

## Comment

We have observed a shorter duration of action of rocuronium in patients receiving anticonvulsant therapy, as is known for many other blockers, compared with other classes of drug which caused no significant interaction. The reasons for this effect may be increased plasma protein binding of the blocker, hepatic enzyme induction or proliferation of acetylcholine receptors on the muscle membrane.[5 6]

Calcium entry blocking drugs, such as verapamil, may have neuromuscular blocking effects and may cause difficulty in antagonism of block.[3 7] However, nifedipine, the drug used by the majority of patients in our study, has been shown not to interact significantly with vecuronium in humans[8] although that does not exclude the possibility of an interaction between rocuronium and verapamil.

Although there is some experimental evidence on the interaction of propranolol with neuromuscular blocking agents, it seems unlikely from our results and absence of previous clinical reports with other blockers that there is any important interaction between beta-receptor blocking and neuromuscular blocking drugs.

## Acknowledgements

Financial support and supplies of rocuronium were received from Organon Teknika NV, Belgium.

# Low-dose rocuronium improves conditions for tracheal intubation after induction of anaesthesia with propofol and alfentanil†

K. BARCLAY, K. EGGERS AND T. ASAI

## Summary

We studied 60 adult patients to assess if low doses of rocuronium improved conditions for tracheal intubation during induction of anaesthesia with propofol 2.5 mg kg$^{-1}$ and alfentanil 10 μg kg$^{-1}$. In a double-blind, randomized design, patients were allocated to one of three groups: group P=saline; group $R_1$=rocuronium 0.1 mg kg$^{-1}$; and group $R_3$=rocuronium 0.3 mg kg$^{-1}$. Intubation conditions were judged as optimal, suboptimal or failure, based on the scoring of ease of jaw opening and laryngoscopy, position of the vocal cords and degree of straining after tracheal intubation. Intubation conditions were judged as optimal in one patient in group P, in six patients in group $R_1$ and in 18 patients in group $R_3$. Conditions were judged as a failure in seven patients in group P, in one patient in group $R_1$ and in none in group $R_3$. No laryngospasm or other complications were observed in any patient. The addition of low doses of rocuronium significantly improved intubation conditions ($P<<0.001$). Ventilation was controlled during surgery, and in no patient was any problem encountered with antagonism of neuromuscular block with neostigmine. Injection of rocuronium 0.3 mg kg$^{-1}$ ($ED_{95}$) with propofol and alfentanil provided a high proportion of optimal intubation conditions. (*Br. J. Anaesth.* 1997; **78**: 92–94)

**Key words**
Anaesthetics i.v., propofol. Analgesics opioid, alfentanil. Intubation tracheal. Neuromuscular block, rocuronium

Tracheal intubation may be accomplished after concurrent injection of alfentanil and propofol (without a neuromuscular blocking agent),[1] but a relatively high dose of alfentanil (40 μg kg$^{-1}$ or greater), which may not be suitable for minor surgery of short duration, is required to obtain reliably satisfactory conditions.[1]

A low dose of neuromuscular blocking agent partially paralyses the laryngeal adductor muscles.[2] Thus concurrent injection of a low dose of a neuromuscular blocking agent, propofol and alfentanil may improve intubation conditions. In addition, the use of low doses of a neuromuscular blocking agent, in theory, shortens the time for recovery from neuromuscular block and reduces the requirement for anticholinesterase drugs. Rocuronium 0.3 mg kg$^{-1}$ is the $ED_{95}$ at the adductor pollicis muscle (as estimated by supramaximal single twitch stimulation at 0.1 Hz)[3] and the $ED_{50}$ at the laryngeal adductor muscles,[2] and is half the recommended intubating dose.[3]

The aim of this study was to examine if injection of a low dose of rocuronium during induction of anaesthesia with propofol and alfentanil improved intubation conditions.

## Methods and results

In a double-blind, randomized design, we studied 60 patients, aged 18–50 yr, after obtaining local Research Ethics Committee approval and written informed consent from all patients. Patients were excluded if they were obese or at risk of pulmonary aspiration, smoked more than 10 cigarettes per day, their tracheas were known to be difficult to intubate or where coughing or straining after tracheal intubation might be detrimental.

Patients were allocated randomly (in blocks of nine) to one of three groups: group P, placebo (10 ml of 0.9% saline); group $R_1$, rocuronium 0.1 mg kg$^{-1}$ made up to 10 ml with saline; group $R_3$, rocuronium 0.3 mg kg$^{-1}$ made up to 10 ml with saline.

Temazepam 20–30 mg was given orally, 1 h before induction of anaesthesia. The patient's lungs were preoxygenated with 100% oxygen via a face mask for 3 min. Immediately after injection of alfentanil 10 μg kg$^{-1}$, propofol 2.5 mg kg$^{-1}$ containing lignocaine 10 mg was injected. If the patient did not lose consciousness after injection of propofol 2.5 mg kg$^{-1}$, the patient was withdrawn from the study. The study drug was then given and the i.v. cannula flushed with saline 20 ml. Anaesthesia was maintained with 50% nitrous oxide in oxygen and an i.v infusion of propofol 10 mg kg$^{-1}$ h$^{-1}$. The lungs were ventilated manually to maintain normocapnia. Two minutes

†Presented in part at the 11th World Congress of Anaesthesiologists, Sydney meeting, April 1996.

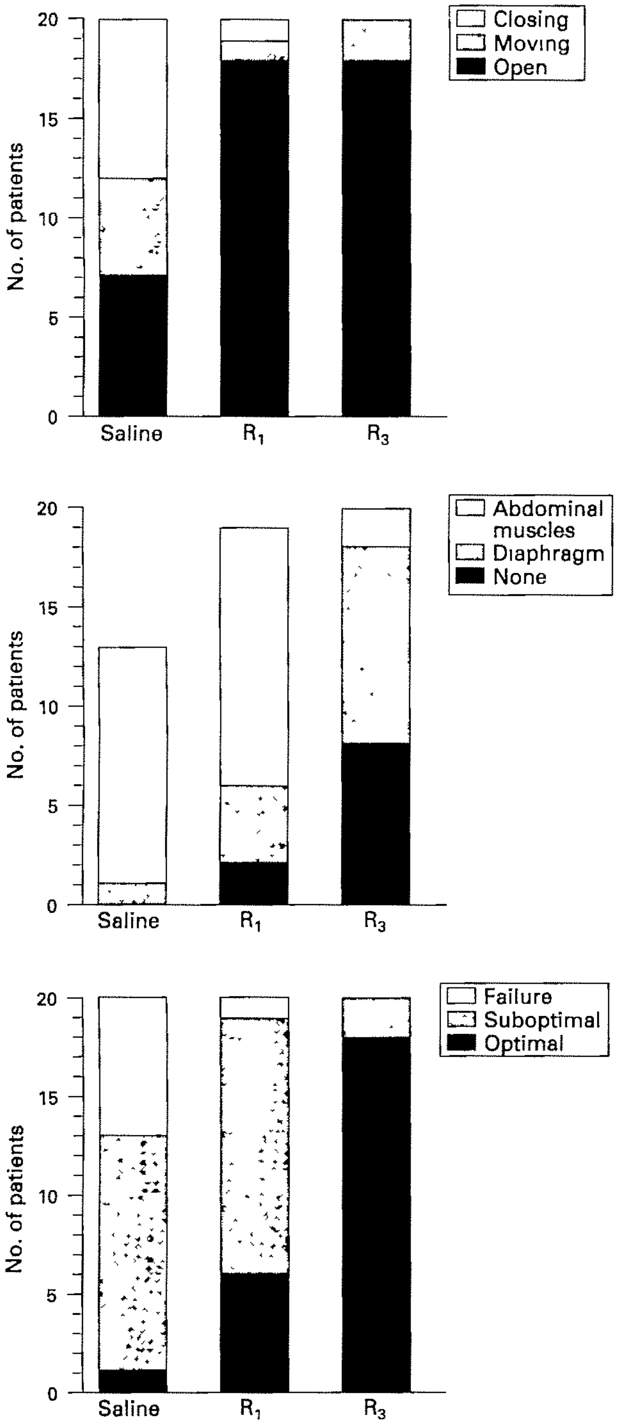

*Figure 1* Position and movement of the vocal cords (top), degree of straining after tracheal intubation (middle) and overall conditions for tracheal intubation (bottom). Saline=no rocuronium, $R_1$=rocuronium 0.1 mg $kg^{-1}$ and $R_3$=rocuronium 0.3 mg $kg^{-1}$. In all groups, propofol 2.5 mg $kg^{-1}$ and alfentanil 10 µg $kg^{-1}$ were given.

after administration of the study drug, an investigator, who was blinded as to the allocation, opened the patient's mouth and attempted to intubate the trachea using a Macintosh laryngoscope. A 9.0-mm id tracheal tube was used in males and a 8.0-mm id tube in females. Tracheal intubation was not attempted if the vocal cords were nearly or fully closed and if there was a possibility of injury to the vocal cords.

The investigator assessed three factors: ease of jaw opening and laryngoscopy (1=easy; 2=fair; 3=difficult), position of the vocal cords and their movement (1=open; 2=moving; 3=closing) and degree of straining ("bucking") after tracheal intubation and cuff inflation (1=none; 2=with diaphragm; 3=with abdominal muscles). The occurrence of any significant complication was recorded.

Overall conditions for tracheal intubation were scored in three grades: optimal, suboptimal and failure. Tracheal intubation was judged as optimal when all scores were 1 or 2, and judged as suboptimal if any of the scores were 3. Failure to intubate was scored as a failure.

Chi-square test for trend was used to compare intubation conditions between group P and groups $R_1$ and $R_3$ (pooled) and if this proved significant, it was used to compare intubation conditions between groups $R_1$ and $R_3$. $P<0.05$ was considered significant. Confidence intervals (CI) for the proportion of optimal intubation conditions in groups $R_1$ and $R_3$ were also calculated.

We expected that intubation conditions would be optimal in 30% of patients in group P and in 80% of patients in group $R_3$.[4] Thus 20 patients in each group would be sufficient to detect a difference of 50% between groups P and $R_3$ with a power of 80–90% at $P$=0.05.

Each group consisted of 20 patients: mean ages in the three groups were similar (27 yr (group P), 30 yr (group $R_1$) and 29 yr (group $R_3$)), but mean weights were different (64 kg (group P), 74 kg (group $R_1$) and 72 kg (group $R_3$)).

Rocuronium 0.1 and 0.3 mg $kg^{-1}$ (pooled) significantly improved intubation conditions ($P<<0.001$) (fig. 1). Intubation conditions were significantly better in group $R_3$ than in group $R_1$ ($P<0.001$). Laryngoscopy was easy in all patients. The proportions of optimal intubation conditions were 30% (95% CI 10–50%) in group $R_1$ and 90% (68–99%) in group $R_3$. In no patient did laryngospasm, bronchospasm, hypoxaemia or other significant complications occur.

## Comment

We have shown that a low dose of rocuronium during induction of anaesthesia with propofol 2.5 mg $kg^{-1}$ and alfentanil 10 µg $kg^{-1}$ improved conditions for tracheal intubation, and that rocuronium 0.3 mg $kg^{-1}$ (half "initial dose") provided optimal conditions in most patients.

The proportion of optimal intubation conditions after administration of propofol 2.5 mg $kg^{-1}$ was greater when the time between injection of propofol and tracheal intubation was short.[5] Therefore, the choice of a neuromuscular blocking agent with a short onset time may be necessary to obtain a high proportion of optimal intubation conditions. Rocuronium 0.25 mg $kg^{-1}$ has an onset time to maximum neuromuscular block of the laryngeal adductor muscles of 1.6 min, which is shorter than that of other non-depolarizing neuromuscular blocking agents currently available.[2 6]

Onset time shortens as the dose of rocuronium increases for doses producing complete neuromuscular block; however, when lower doses which are insufficient to produce complete block are given ($<0.68$ mg $kg^{-1}$, $ED_{90}$ at the laryngeal adductor muscles[2]), onset time is similar, regardless of the dose.[6]

In this study, rocuronium 0.1 mg $kg^{-1}$ appeared to relax the laryngeal adductor muscles; however, rocuronium 0.3 mg $kg^{-1}$ would be required to minimize the incidence of straining after tracheal intubation.

After injection of rocuronium 0.25 mg $kg^{-1}$, maximum neuromuscular block of the adductor pollicis is approximately 70%, and the time to spontaneous 90% recovery of T1 twitch height at this muscle is about 10 min.[2] Therefore, it should be possible to antagonize neuromuscular block immediately after injection of this dose of rocuronium, and the incidence of residual neuromuscular block after surgery is likely to be low. In this study, ventilation was controlled during surgery, and in no patient were there problems with antagonism of neuromuscular block with neostigmine, although we did not study this formally.

## Acknowledgements

We thank Dr M. Harmer, Senior Lecturer, Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, for his encouragement and supervision of the study. We also thank Organon Teknika for their generous supply of rocuronium.

# Effects of desflurane and isoflurane on splanchnic microcirculation during major surgery

J. O'Riordan, H. A. O'Beirne, Y. Young and M. C. Bellamy

## Summary

Isoflurane has been considered the agent of choice where preservation of splanchnic blood flow is required. Liver blood flow and the hepatic artery buffer response are maintained better in the presence of isoflurane than with other volatile anaesthetic agents. The effects of desflurane have not been assessed in humans. Therefore, we have compared the effects of isoflurane and desflurane anaesthesia on small bowel and hepatic microcirculatory flow during major surgery using laser Doppler flowmetry in a prospective, randomized, single-blind, crossover study. Patients were allocated randomly to receive desflurane or isoflurane (1 MAC) in oxygen-enriched air. Steady-state jejunal and liver blood flow in segment III were assessed by laser Doppler flowmetry. Volatile anaesthetics were then interchanged, and measurements repeated at steady state. Desflurane anaesthesia at 1 MAC was associated with significantly greater gut blood flow than 1 MAC of isoflurane. These differences could not be explained by systemic haemodynamic differences. The similarity in total hepatic flow between groups implies an intact hepatic artery buffer response with desflurane and isoflurane. (*Br. J. Anaesth.* 1997; **78**: 95–96)

**Key words**
Anaesthetics volatile, desflurane. Anaesthetics volatile, isoflurane. Liver, blood flow.

Surgery and anaesthesia are known to compromise hepatic blood flow. Patients with pre-existing hepatic dysfunction have a high morbidity and mortality rate. Liver function is compromised when splanchnic blood flow is reduced; major surgery is associated with a significant increase in serum concentrations of liver enzymes.[1]

Inhalation agents affect splanchnic vascular tone to varying degrees. Increased splanchnic vasodilatation may increase portal venous flow to the liver, as occurs with isoflurane. Isoflurane maintains the hepatic artery buffer response better than other volatile anaesthetic agents.[2] The effects of desflurane on the buffer response and liver blood flow have not been assessed in humans. Therefore, we have compared the effects of isoflurane and desflurane anaesthesia on small bowel and hepatic microcirculatory flow during major surgery in human using laser Doppler flowmetry (LDF). The laser Doppler flowmeter (PF3, Perimed, Jarfalla, Sweden) uses a helium/neon laser (632.8 nm). This light is guided to the measurement site via 1.75 m of optical fibre. Two identical adjacent fibres receive backscattered light from the tissues, which is transmitted to independent photodetectors. This backscattered portion consists of light scattered from the static tissue matrix, which has not been Doppler-shifted, and a spectrally broadened component resulting from interactions with moving red blood cells. Optical mixing of these components at the photodetector surface produces an electrical signal which results in an output voltage. This varies linearly with the product of mean red blood cell velocity and red blood cell concentration.

The laser Doppler produces an arbitrary scale of perfusion units (PU), a deflection of 2.5 V=250 PU, set when calibrating the machine with latex microspheres 2 μm supplied by the manufacturer. While this is generally accepted as a measure of flow in tissue microcirculation, LDF provides an accurate estimation of total liver blood flow in humans.[3]

## Methods and results

After obtaining Ethics Committee approval and informed patient consent for this prospective, randomized single-blind, crossover study, we studied 10 adult patients undergoing elective major upper abdominal surgery. Patients with liver disease were excluded.

After premedication with temazepam 20 mg orally, anaesthesia was induced with thiopentone 3 mg $kg^{-1}$ and fentanyl 3 μg $kg^{-1}$. Neuromuscular block was produced by atracurium 0.5 mg $kg^{-1}$ followed by an infusion of 0.4 mg $kg^{-1}$ $h^{-1}$. Patients were allocated randomly to receive either desflurane or isoflurane (1 MAC) in oxygen-enriched air. (1 MAC was taken as the end-tidal concentration of the volatile agent in oxygen, adjusted for age,

Correspondence to M. C. B.

*Table 1* Laser Doppler flow in the jejunum and liver segment III during desflurane or isoflurane anaesthesia (median (interquartile range))

| | Blood flow (PU) | *P* |
|---|---|---|
| Gut (isoflurane) | 94 (75–154) | 0.02 |
| Gut (desflurane) | 186 (146–262) | |
| Liver (isoflurane) | 137 (58–168) | 0.26 |
| Liver (desflurane) | 175 (54–453) | |

according to our pharmacy data sheets.) Randomization was achieved using pre-sealed envelopes containing instructions for the order of administration of volatile agent. A radial artery cannula and central venous catheter were inserted. Direct pressure readings were measured (Spacelabs Medical 90309, Redmond, WA, USA). Inspired and end-tidal concentrations of volatile agent and end-tidal carbon dioxide concentrations were monitored using Datex modules fitted to an Ohmeda Modulus CD anaesthetic machine (Ohmeda, Madison WI, USA). The lungs were ventilated to maintain normocapnia.

After surgical incision and exposure of the liver, jejunal blood flow and segment III liver blood flow were measured by laser Doppler flowmetry.

All measurements were performed at steady state (inspired/end-tidal concentration <1.1). Volatile agents were then interchanged and measurements repeated when steady state had been produced with the second volatile agent.

Blood flow data were analysed using the paired Wilcoxon signed rank sum test and backward stepwise multiple regression analysis (SPSS for Windows 6.0). Variables included mean arterial pressure, central venous pressure and gut perfusion units. Results are expressed as median (interquartile range). Haemodynamic variables were compared using Wilcoxan's signed rank sum test and expressed as mean (interquartile range). There were no differences in mean arterial pressure (78 (70–89) mm Hg for isoflurane compared with 74 (65–81) mm Hg for desflurane), central venous pressure (8.5 (2–12) mm Hg compared with 8.5 (3–10) mm Hg) or heart rate (82 (70–89) beat $\text{min}^{-1}$ *vs* 83 (62–101) beat $\text{min}^{-1}$) between periods of isoflurane compared with desflurane administration. However, gut blood flow was significantly higher during desflurane than during isoflurane administration. Differences in liver blood flow were much less marked (table 1).

Multiple regression described liver blood flow as (1.3×gut blood flow)−24, $P<0.0001$, $r^2=0.85$.

## Comment

In this study we have used laser Doppler flowmetry (LDF) to measure liver and gut microcirculatory blood flow during major surgery with two different volatile agents in humans. We have shown that during major surgery, desflurane anaesthesia at 1 MAC was associated with significantly greater gut flow than 1 MAC of isoflurane. As there were no systemic haemodynamic differences between the two agents, it is likely that differences in gut blood flow were mediated by a local mechanism.

Liver microcirculatory flow, as measured by LDF in a previous study, correlated well with perfusion pressure.[4] Hepatic perfusion in this study was slightly greater during desflurane than during isoflurane administration, but this was not significant. Increasing portal blood flow tends to reduce hepatic arterial blood flow in the presence of an intact hepatic artery buffer response, thus maintaining near constant total hepatic blood flow. Although a type II error cannot be excluded, the similarity in total hepatic flow between agents implies an intact hepatic artery buffer response with desflurane and isoflurane. This has been shown previously in dogs, but not in humans.[5] The hepatic artery buffer response is a semi-reciprocal autoregulatory mechanism whereby changes in portal flow inversely affect hepatic arterial flow. This is mediated at the level of the hepatic arteriole and is thought to be a non-neuronal, adenosine-dependent process.[2]

Multiple regression analysis indicated that gut blood flow accounted for 85% of the variability in liver blood flow. This suggests that liver blood flow in this model was largely portal in origin.

Any technique which preserves gut and liver blood flow may reduce morbidity and mortality.[6] These results indicate that desflurane may be beneficial, particularly in high-risk patients.

# Effect of low-dose dopamine on serum concentrations of prolactin in critically ill patients

A. R. BAILEY AND K. R. BURCHETT

## Summary

Dopamine is a naturally occurring catecholamine with actions in the central nervous system and endocrine systems, including inhibition of prolactin release from the pituitary gland. Prolactin secretion has been shown to be increased in response to physiological stress, while hypoprolactinaemia is associated with a reduction in the cellular immune response. We have investigated the effects of low-dose infusion of dopamine 2.5 $\mu g\ kg^{-1}\ min^{-1}$ on serum concentrations of prolactin in critically ill patients. Six hours after commencing the dopamine infusion, mean serum prolactin concentration had decreased from 746.95 to 128.9 mu. $litre^{-1}$ (normal range 84–488 mu. $litre^{-1}$). This represented a mean reduction of 79.2%, with 35% of patients exhibiting a subnormal concentration while receiving dopamine. This reduction was reversed after cessation of dopamine and reproducible on re-institution. This suppression of the release of dopamine may be a detrimental side effect of low-dose dopamine infusion in critically ill patients. (*Br. J. Anaesth.* 1997; **78**: 97–99)

**Key words**
Sympathetic nervous system, dopamine. Pharmacology, dopamine. Hormones, prolactin. Intensive care.

Dopamine is a naturally occurring catecholamine, the immediate precursor of noradrenaline, which acts as a neurotransmitter in the central nervous system and is also secreted by the adrenal medulla. In addition, dopamine has effects on the hypophyseal–pituitary axis, being involved in the regulation of release of prolactin, growth hormone and thyroid stimulating hormone.

Dopamine acts on $\beta_1$, and to a lesser extent $\beta_2$, adrenergic receptors, $\alpha$ receptors and dopaminergic DA1 and DA2 receptors. Hence dopamine has inotropic, chronotropic and vasoconstrictor properties via adrenergic receptors, while by activation of DA1 receptors, dopamine can produce renal and splanchnic vasodilatation. These effects are dose-dependent, with dopaminergic effects predominating at low dose (0.5–3.0 $\mu g\ kg^{-1}\ min^{-1}$).[1]

Low-dose dopamine is used commonly for its renal vasodilating property in critically ill patient, to maintain renal blood flow, glomerular filtration rate and urine output. However, there is no evidence that incipient renal failure can be aborted, or outcome modified, while arrhythmia, myocardial ischaemia, depression of respiratory drive, increased intrapulmonary shunting and digital necrosis have been reported as side effects of dopamine.[2] Therefore, the continued use of dopamine to "protect" the kidneys must be viewed critically.

The release of prolactin from the pituitary gland is regulated by both the reproductive hormones and central nervous system amines, including dopamine, acting via DA2 receptors on lactograph cells. Stress, surgery and a variety of anaesthetic drugs, including opioids, also increase serum concentrations of prolactin.[3]

Prolactin has been shown to be an immunoregulatory hormone, and hypoprolactinaemia may compromise cellular immune function. In mice, dopamine agonists suppress T-cell-dependent induction of macrophage tumour killing activity and lymphocyte proliferation, while co-administration of prolactin reverses these effects.[4]

Devins and colleagues,[5] using dopamine infusions of $>5\ \mu g\ kg^{-1}\ min^{-1}$, have shown greater than 90% reduction in serum prolactin concentration, with an immediate, but transitory decrease in T-cell response and lymphocyte count. These were reversible after cessation of dopamine. Similarly, data from critically ill infants and children showed that dopamine induced suppression of prolactin release, which is of particular concern as hypoprolactinaemia has been associated with poor clinical outcome in preterm infants through effects on surfactant synthesis, water regulation and gastrointestinal maturation.[6]

The aim of this study was to assess the effect of low "renal" dose dopamine on serum concentrations of prolactin.

## Methods and results

After obtaining local Ethics Committee approval, all adult patients admitted to our intensive care unit

A. R. BAILEY*, BSC, MB, BS, FRCA, K. R. BURCHETT, MB, CHB, FRCA, Queen Elizabeth Hospital, Gayton Road, Kings Lynn, Norfolk PE30 4ET. Accepted for publication: September 13, 1996.

*Present address. Department of Anaesthetics, Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QQ.

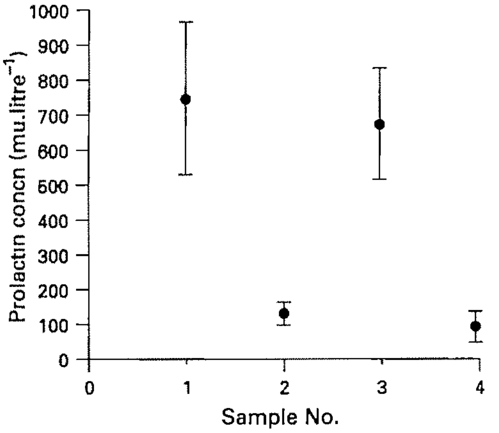

*Figure 1* Changes in mean (95% confidence interval) serum concentrations of prolactin in critically ill patients, after infusion of dopamine 2.5 $\mu$g kg$^{-1}$ min$^{-1}$ Sample 1=baseline serum prolactin concentration, sample 2=after 6 h of infusion of dopamine, sample 3=after a 6-h period without dopamine and sample 4=after another 6 h of dopamine.

(ICU) who were oliguric (<0.5 ml kg$^{-1}$ h$^{-1}$ for more than 2 h) or considered to be at risk of renal impairment because of hypotension (systolic arterial pressure <100 mm Hg), systemic inflammatory response syndrome or after aortic surgery, were considered for entry into the study.

Patients who received dopamine agonist or antagonist drugs before or during the study were excluded and incomplete results from patients who died during the study were not included in the analysis.

After admission to the study, a serum sample was obtained for prolactin assay (sample 1). Dopamine infusion was then commenced at 2.5 $\mu$g kg$^{-1}$ min$^{-1}$ via a central venous catheter, after correction of hypovolaemia with i.v. fluids and treatment of persisting hypotension with non-dopamine inotropes. Standard supportive and specific treatments were implemented as required. After 6 h, serum sample 2 was obtained and dopamine infusion discontinued for another 6 h. After this time serum sample 3 was obtained. Dopamine infusion was then recommenced and the final serum sample (sample 4) was obtained 6 h later. All samples were separated, frozen and analysed in batches for serum prolactin concentration, using an Immulite Prolactin Chemiluminescent Enzyme Immunometric Assay System (Diagnostic Products Corp., LA, USA).

The results were analysed using a paired *t* test.

The study did not involve administration of dopamine to any patient who would not normally have received the drug in their management in our ICU. Any patient who developed oliguria or anuria which did not respond to i.v. fluids, correction of hypotension and i.v. diuretic was recommenced on dopamine infusion and removed from the study.

During the 3-month period, December 1995 to March 1996, 82 patients were admitted to the ICU, of whom 20 (seven female) were included in the study. Age ranged from 16 to 83 yr (mean 60.3 yr) and patients had a median APACHE II score of 18.5 (range 10–24). Two other patients died within 18 h of admission to the study and their results were excluded.

Mean serum prolactin concentration was 746.95 mu. litre$^{-1}$ (95% confidence interval 532–962 mu. litre$^{-1}$) before commencement of dopamine, with 60% of patients having a supranormal level (normal range 84–488 mu. litre$^{-1}$). After 6 h of dopamine infusion, there was a reduction in serum prolactin concentration in all patients by a mean of 79.2 (SD 12.5) % (fig. 1). At this time, 35% of patients exhibited a subnormal serum prolactin concentration. However, this reduction was reversed after cessation of the dopamine infusion for 6 h, with an increase to supranormal levels in 70% of patients. After another 6 h of low-dose dopamine, mean serum concentration of prolactin decreased again, by 83.9 (10.3) %, with 50% of patients exhibiting concentrations less than the normal range.

Measured changes in serum prolactin concentration were all statistically significant at the $P<0.001$ level.

## Comment

The results of this study demonstrate that low-(renal) dose dopamine (2.5 $\mu$g kg$^{-1}$ min$^{-1}$) markedly reduced serum concentrations of prolactin. This effect was both reversible after cessation of dopamine and reproducible after its recommencement. These findings are in accordance with those of other workers[5 6] who used twice the rate of infusion used in this study. Indeed, the magnitude of suppression of serum prolactin in our study was almost as great as that found by Devins and colleagues[5] (79–84% compared with greater than 90%), despite using a lower dose.

It is interesting to note that without dopamine, 60–70% of patients exhibited supranormal prolactin concentrations, whereas with dopamine, serum prolactin concentration decreased to normal and even subnormal concentrations. Prolactin is an immunomodulatory hormone involved in the endocrine response to stress and consequently, any suppression of cellular immunity associated with a reduction in serum prolactin would be undesirable and may predispose critically ill patients to infective complications. Therefore, it seems that in the absence of controlled clinical trials confirming the efficacy of low-dose dopamine as a renal protective agent, its continued use for this purpose should be questioned.

# Coupling of spontaneous ventilation to heart beat during benzodiazepine sedation

D. C. GALLETLY AND P. D. LARSEN

**Summary**

We have examined in eight male volunteers the effect of midazolam sedation on the relationship between timing of spontaneous ventilations and heart beat. On 2 study days, subjects received either midazolam 0.1 mg $kg^{-1}$ or saline placebo while recordings were made of ECG and ventilatory impedance pneumography. We observed in all midazolam-treated subjects clear evidence of synchronous or non-synchronous coupling between ventilation and heart beat. Non-synchronous coupling was seen in two placebo-treated subjects, one of whom had slept during the recording period. We conclude that cardioventilatory coupling is a major determinant of ventilatory timing in sedated subjects. (*Br. J. Anaesth.* 1997; **78**: 100–101)

**Key words**
Hypnotics benzodiazepine, midazolam. Heart, heart rate. Ventilation, spontaneous.

During midazolam sedation in volunteers, we have previously observed phasic coupling of ventilatory amplitude with slow oscillations (approximately 0.02 Hz) in arterial pressure, heart rate and digital plethysmography.[1] We postulated that linking of cardiorespiratory periodicities might be a result of coupling between regulatory centres within the brain stem. In this study we examined further the effect of midazolam on the relationship between ventilation and heart rate. Specifically, we examined the effect of the benzodiazepine on synchronization between heart beat and ventilation.

## Methods and results

After obtaining Ethics Committee approval and informed consent, we studied eight healthy fasting male volunteers, mean age 22 (range 20–27) yr and mean weight 71 (67–79) kg. On 2 study days, supine subjects breathed oxygen 5 litre $min^{-1}$ from a Hudson mask. ECG (CM5) and ventilation (impedance pneumograph, Corometrics Neo-Trak 502) were recorded using a Macintosh IIcx computer (16 bit ADC, sampling rate of 500 Hz). Recording began after a 15-min stabilization period. Twenty minutes later subjects received midazolam 0.1 mg $kg^{-1}$ i.v. or an equivalent volume of normal saline. Twenty minutes later, flumazenil 0.5 mg or saline was administered i.v. The order of administration of drug and placebo was randomized to ensure an equal number of subjects received placebo or active drug on the first occasion.

Observation of cardioventilatory synchronization was based on a method described by Kenner, Pessenhofer and Schwaberger.[2] From the stored ECG data, we determined the timing of each R wave. The ventilatory signal was filtered to remove cardiovascular artefacts and the time of the peak of each inspiration was determined. We calculated for each R wave the time interval until the next ventilatory peak (RV interval). The RV interval for consecutive R waves was plotted against time of R wave occurrence. Synchronization of heart rate and ventilation is shown as tight horizontal banding of the RV interval, indicating a constant time relationship between heart beat and the following ventilation. The number of bands indicates the entrainment ratio or number of heart beats within each ventilatory period.

Cardioventilatory synchronization was observed in two of eight subjects after administration of midazolam; one subject synchronized with a heart rate/ventilatory frequency ratio of 4:1 (fig. 1) and another at a ratio of 3:1. In both, synchronization persisted throughout the sedation period. Synchronization was not observed after placebo.

In the six other midazolam-treated subjects and in two placebo controls (one of whom had slept during the recording period), less distinct bands were observed in the RV plots. This is seen also in the subject in figure 1 in the 10 min before administration of midazolam. Closer examination of these bands showed them to be composed of variable numbers of heart beats during each ventilatory period (generally 3, 4 or 5). Despite this variability, RV intervals were within discrete bands. As we consider that these indicate a form of coupling between ventilation and heart beats, we refer to this phenomena as non-synchronous coupling (NSC).

In all midazolam-treated subjects, flumazenil ended the period of synchronization or reduced the clarity of the NSC bands.

During the period of synchronization shown in

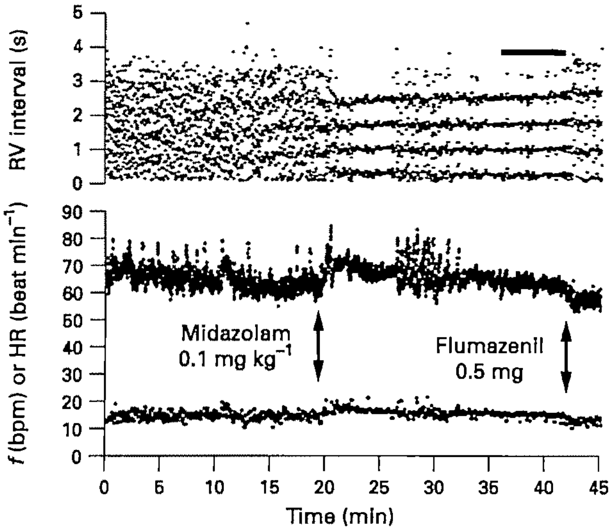

*Figure 1* RV interval, ventilatory frequency (*f*) and heart rate (HR) in a subject showing non-synchronous coupling (12–20 min) and 4:1 cardioventilatory synchronization after administration of midazolam. Occasional periods of 5:1 coupling are shown under the horizontal line.

figure 1, the ratio of heart beat to ventilation alternated between two whole number ratios (shown as a fifth sparse band between 35 and 40 min). During this episode, ventilation was constantly synchronized to every fourth heart beat but occasionally the following ventilation would be delayed while it "waited" for a fifth.

## Comment

Entrainment phenomena occur frequently in physical, mathematical and biological systems where two oscillators are coupled.[3] Many such entrainment phenomena have been described in physiology; breathing rate and heart rate may become entrained with step rate during running, cycling or rowing. In sleeping adults, the onset of inspiration most frequently occurs during the diastolic phase of the cardiac cycle[4] and the equivalent of our non-synchronous coupling has been described in sleeping infants.[5]

Some cardioventilatory interaction is necessary as conditions which increase heart rate tend also to demand increased ventilatory frequency. The benefits of NSC and synchronization are less clear. Several authors have argued that synchronization of locomotor and respiratory rhythms may cause a beneficial improvement in energy utilization, and in relation to our own observations, optimal pulmonary blood flow, gas exchange or cardiac work might best occur with a heart beat occurring during a particular phase of respiration. We believe that cardioventilatory coupling may be important for optimal performance of the thoracic pump which may require heart beat to fall within the range of the inspiratory period. If coupling is of benefit to the thoracic pump then plainly this effect is minimal in the awake and alert state. NSC and synchronization were observed only in subjects who were sedated or who had lain quietly for several minutes. This may suggest the role of coupling is evolutionally vestigial, or its role is important only during sleep.

The nature of the interaction between cardiac and respiratory rhythm generators is not understood with certainty. It is known that cardioventilatory entrainment ceases in animals when bilateral vagotomy is performed.[2] Thus efferent or afferent input from pulmonary stretch receptors or baroreceptors may play a part in the feedback interaction. In our study, NSC and synchronization were observed despite the mild vagolytic effect of midazolam (an increase in heart rate occurred in all midazolam-treated subjects and in none of the controls) (fig 1). Kenner, Pessenhofer and Schwaberger[2] found in rabbits "rapid and transient variations in the ventilatory rate appear to be mainly responsible for rapid entrainment". Similarly in humans we observed that entrainment of ventilation by heart rate clearly occurred where the respiratory period alternated between whole number ratios equal to the the heart period while heart rate remained relatively constant.

Goodman[6] noted that some anaesthetized patients exhibit a "bimodality of ventilatory frequency", that is ventilatory frequency settled at two possible values between which it variably alternated. Although the author suggested that this indicated the existence of a multi-frequency oscillator within the respiratory centre, the effect can be explained easily by cardioventilatory coupling, with ventilatory frequency varying between two entrainment ratios.

Current concepts of respiratory control focus on an independent respiratory oscillator modulated by chemo- and mechanoreceptor inputs. It is clear, however, that during sleep and sedation, the timing of ventilation is coupled or even synchronized for long periods to cardiovascular events. The clinical relevance of this coupling is unknown, although its recognition may have implications for the interpretation of studies involving analysis of heart rate variability, breathing periodicities and models of their genesis.

CASE REPORTS

# Anaesthetic management of a patient with an automatic implantable cardioverter defibrillator *in situ*

P. C. A. KAM

## Summary

The automatic implantable cardioverter defibrillator (AICD) is becoming used more frequently in patients with refractory malignant ventricular arrhythmias. The anaesthetic implications of patients with an AICD *in situ* presenting for surgery are discussed. (*Br. J. Anaesth.* 1997; **78**: 102–106)

**Key words**
Equipment, defibrillators. Complications, tachycardia.

Malignant recurrent ventricular arrhythmias cause sudden cardiac death in an estimated 40 000 people annually in the United States.[1] Survivors of cardiac arrest secondary to ventricular tachycardias have a 30% risk of a recurrent arrest within 1 yr and a 45% risk at 2 yr.[2 3] The mortality rate is approximately 60% within 2 yr in spite of antiarrhythmic prophylaxis considered adequate at that time.[2 3] A major advance in the management of recurrent malignant ventricular tachycardia has been the development of the automatic implantable cardioverter defibrillator device (AICD) by Mirowski, Mower and Staewen.[4] Since the first device was implanted in 1980, technological advances have led to a marked increase in the insertion of AICD, especially with the availability of systems that do not require thoracotomy for implantation and further miniaturization of the generator.[5] Anaesthetists are therefore likely to encounter patients with an AICD *in situ* presenting for surgery unrelated to the defibrillator.

This article describes the anaesthetic management of a patient with a third-generation AICD *in situ* presenting for total hip replacement and discusses the management issues relevant to anaesthetists.

## Case report

A 62-yr-old man, a Jehovah's Witness with an implanted AICD, presented for left total hip replacement. He had a long history of hypertension and ischaemic heart disease for which he underwent coronary artery bypass surgery 5 yr and resection of a posterobasal ventricular aneurysm 2 yr previously. As he developed recurrent ventricular tachycardia (VT) and fibrillation (VF) with episodes of atrial flutter after the aneurysectomy, a third-generation AICD (Medtronic 7219C) with two transvenous leads and a subcutaneous patch electrode at the cardiac apex was implanted. The AICD was programmed to provide anti-tachycardia pacing of VT at 130–190 beat min$^{-1}$, low energy cardioversion for VT greater than 190 beat min$^{-1}$ and defibrillation at 25–35 J for VF with anti-bradycardia pacing at 50 beat min$^{-1}$. His current medications were sotalol 80 mg twice daily, captopril 25 mg daily, lisinopril 5 mg and frusemide 20 mg daily. He also had a history of mild obstructive sleep apnoea which was confirmed by sleep studies.

On examination, the patient was slightly overweight (90 kg) with an arterial pressure of 150/80 mm Hg and a heart rate of 60 beat min$^{-1}$. His ejection fraction was 30% and preoperative investigations were within normal limits. The preoperative electrocardiogram showed sinus rhythm with Q waves in the inferior leads.

All medications except frusemide were continued and he was premedicated with morphine 10 mg, 1 h before surgery. Before induction of anaesthesia, invasive arterial pressure, central venous pressure via an antecubital catheter, and ECG monitoring together with pulse oximetry were established. Adhesive external defibrillator pads were applied laterally on the chest away from the subcutaneous patches. A left femoral nerve block with 1% lignocaine 25 ml was performed. The patient's lungs were preoxygenated and anaesthesia was induced with increments of thiopentone to a dose of 175 mg i.v. Neuromuscular block was produced with vecuronium 10 mg and tracheal intubation performed. The patient's lungs were ventilated with 0.5–1% isoflurane and nitrous oxide in oxygen, and normocapnia was maintained with the aid of a capnograph. Normothermia (36.1 °C) was maintained with the use of a warm air convective blanket (Bair Hugger, Augustine Medical, USA) and an i.v. fluid warmer.

A programmer from the cardiology department was in attendance and the anti-tachycardia, cardioversion and defibrillation functions of the AICD were deactivated and the anti-bradycardia pacing function left intact. During operation, there was a transient episode of atrial flutter with a slow ventricular rate resulting in mild hypotension (75/50 mm Hg) and this triggered the anti-bradycardia pacing

function of the AICD. The patient responded to metaraminol 0.5 mg and arterial pressure was maintained at 120–150/60 mm Hg with a CVP of 9–19 mm Hg.

Diathermy using bipolar leads was used throughout the procedure. A Muller cemented hip prosthesis was inserted. Blood loss was estimated to be 400 ml and the patient received 1 litre of normal saline. At the end of the procedure, neuromuscular block was antagonized with neostigmine 2.5 mg and glycopyrronium 0.4 mg.

In the recovery ward, the AICD was reactivated to its preoperative parameters. Analgesia was provided with morphine i.m. On the first postoperative day, the AICD was tested to ensure it was functioning appropriately. The patient was monitored in a high dependency area of the orthopaedic ward. However, the patient developed VT on the third and 10th postoperative days which was terminated successfully by anti-tachycardia pacing.

## Discussion

The AICD is proving to be an effective and innovative device for the treatment of patients with drug-resistant malignant ventricular arrhythmias, reducing the 1 yr mortality rate from 66% to approximately 8.5%.[6] An understanding of these devices is essential for anaesthetists who are likely to encounter these patients with an AICD *in situ* presenting for surgery unrelated to the device.

AICD technology[5 7 8] has become increasingly sophisticated and complex (table 1). The original first-generation AICD had only defibrillation capability without any programmability. The second-generation devices had limited programmability of rate threshold parameters and shock energy. The third-generation devices provide anti-bradycardia pacing, anti-tachycardia pacing, low energy cardioversion and standard defibrillation capabilities. The fourth-generation devices use a single right ventricular coil electrode and the body of the generator as the other pole for the delivery of the shock and are referred to as active or hot can devices.[8] Fifth-generation devices which have DDD pacemaker functions and can identify and treat atrial arrhythmias are currently undergoing clinical trials.

The AICD[5] consists of a pulse generator and a lead electrode system for sensing, pacing and delivery of shocks for cardioversion or defibrillation. The pulse generator is made up of a battery source (lithium vanadium silver pentoxide cells), capacitors for high voltage generation, and a storage and microprocessor logic system which analyses incoming signals and makes decisions regarding appropriate therapy based on algorithms set by the cardiologist. Older pulse generators weigh 200 g with a volume of 80–100 ml but newer devices may weigh 100 g with a volume of 60–100 ml. Larger generators are implanted in the left anterior abdominal wall behind the rectus muscle. The newer smaller generators[7 9] can be implanted in the pectoral region either subcutaneously or subpectorally.

Before 1990, the AICD used lead systems comprising epicardial patches which therefore required a thoracotomy. Non-thoracotomy lead systems[9] have become available over the past few years and consist of a ventricular lead with a distal sensing pacing tip and a defibrillation coil placed in the right ventricle. A second defibrillation coil is placed in the superior vena cava (SVC) or right atrium (RA), either on the same lead or on a separate lead positioned in the SVC or anchored to the RA. A third lead system usually comprising an array of leads placed subcutaneously over the cardiac apex may be required to achieve satisfactory defibrillation thresholds. The most recent advance has been the development of the active can system which uses a single ventricular electrode.

The sensing components of the AICD[5 7] continuously monitor and analyse the patient's heart rate (using the R-R interval) and waveform morphology by measuring the variance from baseline. The absence of isoelectric segments is typical of VF or sinusoidal tachycardias. Different emphasis on either the rate detection channel or the waveform channel may be selected by the cardiologist. Emphasis on the rate detection channel improves the detection of non-sinusoidal tachycardia but may sense and inappropriately deliver a shock in sinus tachycardia, supraventricular tachycardia or atrial fibrillation with a rapid ventricular response. With the fourth-generation devices, it is possible to programme to sense the rate of change in heart rate, therefore minimizing delivery of shock while the heart is in sinus rhythm. Dual sensing models have a better

specificity for non-malignant arrhythmias but may not detect non-sinusoidal ventricular tachycardia. A malignant ventricular tachycardia is usually present for 5–15 s before the preset rate and morphology criteria are met, at which point the AICD charges its capacitor and delivers a shock of 25 J. The entire process takes 35 s and if VT persists, subsequent shocks of 30 J are delivered. After four shocks, the AICD resets in 35 s and if VT persists, another series of four shocks are delivered. The characteristics of the shock waveform (monophasic/biphasic) and current pathway (single, bidirectional or sequential) used in the AICD vary depending on the model and lead system used. The latest advanced AICD are capable of different responses to one or more tachycardias classified by rate and a programmable sequence or graded (or "tiered") therapy to an arrhythmia by providing adaptive pacing sequences to low energy cardioversion to high energy defibrillation. With the fourth-generation devices, the use of the large surface area of the "can" or body of the device as a pole for delivery of the shock decreases defibrillation thresholds and conserves battery life. If the malignant VT is shown to be terminated by pacing in the electrophysiology laboratory, algorithms may used to attempt pace termination of malignant arrhythmia. However, current devices may not be able to distinguish some forms of supraventricular and ventricular tachycardias, although atrial fibrillation may be identifiable if the variability in the RR interval is programmed into the device.

In the preoperative evaluation of patients[10] with AICD presenting for non-cardiac surgery, the underlying cardiac disease (ischaemic or valvular heart disease, cardiomyopathy) and the status of their ventricular function should be taken into account. It is important that these patients are receiving optimal medical therapy and a knowledge of preoperative antiarrhythmic medications for each individual patient would be useful if intraoperative VT or VF occurs. Preoperative investigations should be directed towards detecting any electrolyte imbalance or drug toxicity which may predispose to intraoperative complications or cause inappropriate discharge of the AICD. In the patient described, frusemide was omitted to reduce problems associated with hypovolaemia and haemodynamic instability. Patients with AICD frequently suffer from depression[11] as a result of the stresses associated with frequent discharges of the AICD and may be receiving antidepressant medication.

A knowledge of the model of the AICD is important as there is wide variation in the functional characteristics of different models.[5 7] Patients usually carry a medic alert bracelet[12] and identification data that would provide information on the model, lead systems, therapy options and contact details of the cardiologist. It would be prudent for the anaesthetist to consult the cardiologist involved. An over-penetrated radiograph of the pulse generator would identify the model of the AICD.[13] A chest x-ray would reveal the lead systems, position of the patches and pulse generator which are important for the intraoperative management of these patients.

AICD malfunction may be related to battery depletion, failure of sensing as a result of altered thresholds, and fracture or migration of lead systems. Cardiac symptoms may indicate the complications of AICD implantation such as infection, pericarditis, pericardial effusion, cardiac fibrosis or progression of the underlying cardiac disease.

Although there is little information available,[10] the anaesthetic management of patients with an AICD *in situ* is similar to that for patients with rate responsive permanent pacemakers.[14] In minor and short surgical procedures, monitoring should consist of ECG and pulse oximetry with a device that has a plethysmographic display. For major surgical procedures or patients with severe impairment of left ventricular function, intra-arterial pressure monitoring is mandatory as it would demonstrate the adequacy of perfusion in the event of intraoperative tachyarrhythmia. Central venous access and pressure monitoring is useful as it provides a route for vasoactive drugs and may aid in the optimization of fluid therapy. The use of a pulmonary artery catheter is dictated by the patient's cardiac function but its benefits must be weighed against the risks of inducing VT or VF and displacing the lead systems of the AICD during its insertion. An external cardioverter/defibrillator should be available in the operating theatre. Adhesive external defibrillator patches should be placed appropriately on the patient's chest and it is important to ensure that the appropriate connectors are available. These enable effective cardioversion/defibrillation without contamination or interference of the surgical field.

Although no specific anaesthetic techniques have been advocated, the main objectives are to avoid factors and drugs that induce VT or VF and to maintain haemodynamic stability. Adequate analgesia is essential to reduce sympathetic overactivity during and after operation.

In general, all AICD should be deactivated[8 12] during surgery as they can inappropriately discharge because of extraneous signals, such as myopotentials caused by shivering, or fasciculations induced by suxamethonium, diathermy, orthopaedic instrumentation, and by false sensing as a result of sinus tachycardia or rapid atrial fibrillation. However, with the third- and fourth-generation AICD, selective deactivation of the anti-tachycardia, low energy cardioversion and defibrillation functions can be achieved with the anti-bradycardia pacing function remaining activated. This is useful if the patient develops severe bradycardia during operation, as seen in this patient. Deactivation of the AICD is accomplished best using its programming device.[12] Deactivation of the first- and second-generation devices can also be achieved by placing a "ring" or "donut" magnet over the pulse generator for 30 s which is indicated by a continuous tone. Removal of the magnet maintains the pulse generator in its inactive mode. Reactivation of the AICD may be achieved by placing the ring magnet over the inactive pulse generator for 30 s, and pulse tones synchronous with the QRS complexes indicate that the generator is reactivated. However, the tones emitted from these devices are extremely difficult to hear. With the proliferation of new devices, the effects of a magnet are not consistent for all models of AICD.[13] The third- and fourth-generation devices are inhibited and continue to sense but not deliver therapy in the presence of a magnet.

Electromagnetic interference can lead to malfunction of the AICD.[10,13] High frequency electromagnetic interference can inhibit the AICD while lower frequency electromagnetic interference may cause the AICD to incorrectly sense and thus inappropriately deliver a shock. During surgery, if diathermy is used, the AICD should be deactivated to avoid inappropriate discharge and reactivated when diathermy is not required. In the patient described, diathermy was required to minimize intraoperative blood loss as he was a Jehovah's Witness. With the third-generation or multi-function AICD, VT and VF sensing and treatment functions should be programmed off, leaving the anti-bradycardia (VVI) pacing function intact. Diathermy can also cause burns at the myocardial–electrode interface leading to raised pacing thresholds, reprogramming of the AICD and damage to the circuit of the pulse generator. When diathermy is used, the following precautions should be undertaken.[15] Bipolar diathermy with the lowest current output should be used to prevent damage to the pulse generator. The ground or indifferent electrode of the diathermy should be placed as far away as possible from the generator. Diathermy must not be applied close to the generator as it may damage its circuitry and cause burns to the surrounding tissues.

Magnetic resonance imaging is contraindicated in patients with AICD[13] as strong magnetic fields produced can exert mechanical forces causing physical pain and damage to the generator, or cause inappropriate delivery of a shock. Radiotherapy (linear accelerator, betatron, radioactive cobalt) may damage the complementary metal oxide semiconductor circuits of the AICD, especially with cumulative doses.[13,16] Therefore, shielding of the generator should be undertaken and the device evaluated after its exposure to radiation. Theoretically, extracorporeal shock wave lithotripsy can produce mechanical and electromagnetic forces which can damage the piezoelectric crystal timing device of the AICD or cause inappropriate delivery of a discharge. However, bench analysis[17] and a case report[18] suggest that contralateral lithotripsy can be performed safely in patients with an AICD *in situ*. The safety of lithotripsy applied ipsilateral to the AICD is unkown. As electroconvulsive therapy (ECT) frequently induces transient arrhythmias, the AICD should be deactivated just before treatment and reactivated immediately after ECT.[13] Grounding of the patient should be avoided as the delivered current may be rerouted to the heart via the defibrillator electrodes resulting in VF.

The presence of an AICD should not discourage standard cardiopulmonary resuscitation.[12,13] External defibrillation does not damage the AICD and should be administered promptly on the assumption that the implanted device is not operative. With the first- or second-generation AICD, the presence of the epicardial patches may increase the energy required for external defibrillation as a result of the shielding effect of the insulating portions of the patches or the shunting of energy away from the myocardium through the conducting portions of the patches.[13] An anterior–posterior placement of external defibrillation pads has been shown to be efficacious in such patients.[19] In patients with subcutaneous electrodes requiring external defibrillation, significant interaction may occur if the chest paddles are applied over the subcutaneous electrode. After external defibrillation, the pulse generator should be examined for correct function and to ensure that the programmed parameters have not been reset. However, internal defibrillation can damage the AICD. Personnel administering cardiopulmonary resuscitation may experience a mild electric shock on the patient's body surface if an AICD discharges but this should not pose a risk to the personnel during resuscitation. Further, as rapid supraventricular tachycardias (SVT) with adequate perfusion are common during resuscitation, internal defibrillator discharges may be triggered by the SVT and result in VT or VF. Thus in a controlled environment it may be desirable to deactivate the AICD during cardiopulmonary resuscitation.

In the postoperative period, hypoxaemia, hypercapnia and inadequate analgesia causing increased sympathetic activity may predispose to VT and VF. Continuous monitoring is essential until vital signs are stable. Spontaneous skeletal muscle contractions caused by shivering can generate myopotentials which may inappropriately trigger the AICD. Low frequency electromagnetic interference may arise from transcutaneous electrical nerve stimulation (TENS) leading to inappropriate delivery of shocks and therefore are contraindicated.[15] It is imperative that the devices are tested before patients are discharged from hospital.

As automatic implantable cardioverter defibrillator therapy has become more popular and sophisticated, these devices present the anaesthetist with several diagnostic and management issues and hence an understanding of the functions of these devices is essential for the optimal care of the patient.

# Ether in an isoflurane vaporizer and the use of vapour analysers in safe anaesthesia

A. N. STRACHAN AND M. N. RICHMOND

## Summary

A Penlon Sigma isoflurane vaporizer was found to contain some diethyl ether. This had escaped from a ruptured temperature compensation device within the vaporizer. The Datex AS/3 vapour analyser detected the foreign agent and displayed a warning. Different types of vaporizer compensation devices are highlighted and the use of vapour analysers is discussed. We conclude that these analysers are invaluable for indicating that the patient is receiving the correct concentration of an inhalation agent but are of little use in the detection of all but a few possible contaminants. (*Br. J. Anaesth.* 1997; **78**: 107–108)

**Key words**
Equipment, vaporizers. Anaesthetics volatile, diethyl ether. Anaesthetics volatile, isoflurane.

## Case report

A pungent smell of ether was noted from the common gas outlet at a routine anaesthetic machine check with oxygen flowing at 6 litre min$^{-1}$ and the vaporizer turned off. The Datex AS/3 agent analyser registered "alcohol detected". The machine was removed from service and the foreign agent was isolated to the Penlon PPV Sigma isoflurane vaporizer. Subsequent analysis of the contents of the vaporizer indicated the presence of diethyl ether. No other vaporizers in the department were found to have a similar problem.

The vaporizer was taken to be examined by the Medical Devices Agency. With the casing removed, a soldering defect was found in the bellows of the temperature compensation device which contains diethyl ether. Diethyl ether could escape into the bypass orifice and then into the back bar of the anaesthetic machine, even with the vaporizer turned off (fig. 1).

*Figure 1* Schematic diagram showing escape of diethyl ether from the temperature compensation device into the bypass orifice.

## Discussion

This case highlights several issues concerning vaporizers and vapour analyser design, particularly with regard to safe anaesthetic practice. Most anaesthetic vaporizers automatically compensate for temperature. Thermal compensation was first described as part of the Epstein–Macintosh–Oxford inhaler.[1] The diethyl ether filled bellows expands and contracts in one plane producing a linear change in gas flow resistance, allowing relatively simple calibration. Penlon continue to use this device in most of their vaporizers. In contrast, other manufacturers use bimetallic devices, with metals with different thermal coefficients of expansion (usually invar and brass) in varying designs to produce thermal compensation. They produce a non-linear change in gas flow resistance and are only accurate between 15 °C and 35 °C.

Vapour analysers in Britain are based usually on infrared absorption spectrophotometry. Light in the infrared spectrum does not cause damage to vapour molecules (ultraviolet light may ionize molecules and visible light may induce chemical reactions). Asymmetric polyatomic molecules absorb infrared light at characteristic wavelengths. Thus carbon

---

A. N. STRACHAN, MB, CHB, M. N. RICHMOND, MB, CHB, FRCA, Department of Anaesthesia, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF Accepted for publication, September 4, 1996

dioxide has a strong absorption band at 4.26 μm and nitrous oxide has a dominant band at 4.55 μm and a weaker one at 3.9 μm. The volatile anaesthetic agents have a common band at 3.3 μm which corresponds to the stretching of the C—H bond, and a series of overlapping bands in the 7–14 μm range. The change in probe infrared light intensity caused by absorption can be used to determine the concentration of absorbing molecules. The vapour analysers thus use wavelengths in the range 3.3–3.5 μm and others up to 10 μm. They determine concentrations of the commonly used volatile anaesthetic agents and some are able to distinguish automatically between all five.

Infrared vapour analysers cannot detect chemicals outside their working wavelength, and can only detect a few chemicals within it. Unfortunately, some of these agents can interfere with this analysis. These include methane and acetone produced from the patient,[2 3] cyclopropane used for induction,[4] ethanol on the patient's breath and cleaning agents such as isopropyl alcohol used for breathing systems. The Datex AS/3 can detect the presence of methanol, ethanol, diethyl ether, acetone, isopropanol and acetaldehyde. In the presence of one of these contaminants the identification bench cannot ascertain a true concentration of anaesthetic vapour and thus displays an "alcohol detected" warning. Newer AS/3 monitors have an upgraded bench which automatically compensates in its calculations and produces a true vapour concentration. Thus this machine does not warn the anaesthetist even when such a foreign agent is detected.

The Association of Anaesthetists' guidelines state that the "monitoring of vapour concentration is desirable, particularly when low gas flows are used".[5] In surveys of anaesthetic mishaps, many include volatile anaesthetic agents. Five of 16 equipment faults in one survey resulted from a different agent, which had been used previously, being left in an operating mode.[6] Twenty of 507 equipment faults were caused by vapour overdoses and 22 by vaporizers being left in an operating mode unintentionally.[7] In the Australia incident monitoring study, three of 10 cases of awareness were caused by inappropriately low concentrations of inhalation agent.[8] Monitoring minimum alveolar concentration of inhaled agents may be the best currently available method of ensuring anaesthetic depth[9] and invaluable for medicolegal evidence.[10] Vaporizer settings may be inaccurate because of poor calibration,[6] overfilling[11] or emptiness.

In summary, this case has described a fault in a common design of vaporizer and highlights the use of the vapour analyser as a safety device as an indicator of appropriate concentrations of inhalation anaesthetic agent. Its use in detecting contaminants is severely limited but it would seem prudent that if a foreign agent is detected, even if the analyser can compensate, the anaesthetist should be warned.

# CORRESPONDENCE

## Cardiac arrest after Caesarean section under subarachnoid block

Sir,—We wish to comment on the case report by Scull and Carli on cardiac arrest after Caesarean section during subarachnoid block.[1]

There seems to be little in common between the patient described by Scull and Carli and those in their references. In their discussion, Scull and Carli quoted case reports of excessive bradycardia progressing to asystole and differentiated between those patients with good and poor outcomes.[2–5] None of these patients was pregnant and all received sedative medication. Patients with a poor outcome appeared to be more profoundly sedated than those who did well. All those with a good outcome seemed able to converse with the anaesthetist until the time of the adverse event In only one of the patients under discussion was adrenaline used early in the course of resuscitation.[4] In Caplan and colleagues' group of 14 patients, adrenaline was not given until a mean time of 7.5 min after the diagnosis of inadequate circulation.[5]

Perhaps the important lesson to be drawn from this case report is that in any patient with inadequate circulation a resuscitation procedure should be used promptly. Use of either ventricular fibrillation or asystole procedures of the Adult Advanced Cardiac Life Support section of the European Resuscitation Council Guidelines would have resulted in more prompt administration of adrenaline with its beneficial $\alpha$ and $\beta$ agonist effects.[6]

Sir,—The purpose of this case report was to highlight the potential for catastrophic cardiovascular collapse in patients with a high subarachnoid block. On reviewing the literature it became apparent that two groups of patients existed, those who immediately responded to minimal resuscitative measures[1–3] and those that, despite prolonged efforts, faired badly.[4 5] The idea that deeper sedation in the pre-arrest period seems to be linked to poor outcome was entertained briefly by Caplan and colleagues in their first reported series,[4] but was dismissed after analysis of the second series of cases.[5] The case we reported obviously does not fit into either category, indeed it is remarkable because of the duration of resuscitation and the resultant positive outcome.[6] We agree with Trotter and Patey that in the event of cardiovascular collapse, resuscitation procedures, that is early use of adrenaline, should be used.

6. Scull TJ, Carli F. Cardiac arrest after Caesarean section under subarachnoid block. *British Journal of Anaesthesia* 1996; 77: 274–276.

Sir,—I read with interest the clinical report of Scull and Carli[1] describing cardiac arrest in a woman after Caesarean birth under subarachnoid anaesthetic. I wish to make two points. First, the dose of spinal bupivacaine was 15 mg which in my clinical experience is unnecessarily large. I have used 0.75% hyperbaric bupivacaine for Caesarean section in doses ranging from 1.0 ml (for short, oriental women whose obstetricians perform the surgery in less than 45 min) to 1.6 ml (in tall African American women where a larger dose is used to extend the duration of anaesthesia to allow for the inexperience of junior obstetric residents). The height of the sensory block varies among individuals but is always adequate for surgery (i.e. >T4). Interestingly, I have yet to witness maternal bradycardia with these doses, even when the sensory level has reached T2 or above. I wonder if the large dose of bupivacaine, used by these authors, place parturients at greater risk from a dense, high sensory block with an increased potential for bradycardia by mechanisms outlined in their discussion. I would wish to know at what point their patient's T2 sensory level was determined and what was the level 20 min after the block was instituted and at the end of surgery.

Second, the importance of hypomagnesaemia in this case may have been understated. Although serum magnesium concentrations decrease during pregnancy, perhaps as a result of a 25% increase in renal excretion,[2] they do not achieve the low concentration described in this woman (0.25 mmol litre$^{-1}$). Although no other risk factors for hypomagnesaemia were described in this report, they may have been present. For example, was there a history of hyperemesis gravidarum, use of diuretics during pregnancy or a history of alcohol abuse. Other possible causes exist[3] and needed to be excluded. On discovery of such a low serum concentration of magnesium, serum concentrations should be remeasured and, if still low, a 24-h urine collection for magnesium started. If serum magnesium concentration is <0.5 mmol litre$^{-1}$ and 24 h urine magnesium is <0.5 mmol, there is likely to be a total body magnesium deficiency which requires treatment and further investigation. The signs and symptoms of hypomagnesaemia can be subtle and include neuromuscular and psychiatric manifestations. If a pertinent history and physical examination are not carried out these problems can be overlooked. The cardiac manifestations of hypomagnesaemia are well described, especially in patients with heart disease and after cardiac surgery [4]

The initial ECG after collapse of the patient was ventricular fibrillation, well documented as a manifestation of hypomagnesaemia, especially torsade de pointes.[5] The 12-lead ECG findings in this patient were not described and although they are relatively non-specific in the presence of hypomagnesaemia, knowledge of the QT interval would be important. Treatment for ventricular fibrillation secondary to hypomagnesaemia is magnesium sulphate 8 mmol (2 g) i.v. over a 10-min period in 10 ml of 5% glucose in water, followed by 20 mmol in 500 ml over 3 h.

Scull and Carlis' report reminds us of the importance of having cardiopulmonary resuscitation (CPR) equipment available in obstetric suites and the need for regular CPR drills for medical, midwifery and nursing personnel. However, the aetiology of the cardiac arrest in the case they describe is not clear.

Sir,—Thank you for the opportunity to reply to Dr Gambling

While we accept that an adequate block for Caesarean section may be obtained with a number of "recipes", it is our experience that hyperbaric bupivacaine 15 mg giving a block of up to T2 is optimum for the prevailing surgical conditions in our unit. The operative procedure may last up to 2 h with routine exteriorization of the uterus and a dense high block is preferable. Extreme bradycardia is rare, but reductions in maternal heart rate to 70–80 beat min$^{-1}$ are not unusual.

The sensory level of the block was determined with ice immediately before surgery, 15 min after dural puncture. The level was not checked during operation or at the end of the procedure. However, we do feel it is prudent to both check and document sensory levels at regular intervals during the operative phase and into the recovery period; this may provide useful information on recovery of sympathetic tone and hence the likelihood of triggering the detrimental circulatory reflexes discussed.

As reported in the case, the only abnormal finding on investigation of aetiology of the arrest was a low serum concentration of magnesium (0.25 mmol litre$^{-1}$). The patient had no risk factors for hypomagnesaemia such as those suggested by Dr Gambling She was investigated extensively for renal causes of hypomagnesaemia with no positive findings. After one bolus of magnesium in the post-arrest period, her serum magnesium concentration returned to and remained within normal limits. The 12-lead ECG revealed a sinus tachycardia with no QT abnormalities.

We agree with Dr Gambling that the aetiology of the cardiovascular collapse in this case is far from clear, although non-specific circulatory mechanisms as detailed in the case discussion[1] are the most likely cause.

1. Scull TJ, Carli F. Cardiac arrest after Caesarean section under subarachnoid block. *British Journal of Anaesthesia* 1996; 77 274–276.

Sir,—We read the case report by Scull and Carli[1] and wish to make the following observations. Many factors may have contributed to the cardiac arrest in this patient but one factor may have been the choice of agents: 0.75% hyperbaric bupivacaine 2 ml and preservative-free morphine 0.25 mg to establish the subarachnoid block. These agents were chosen presumably to prolong the block (we sympathize with them in that the Caesarean section took 1 h 35 min) and provide postoperative analgesia. Bupivacaine 0.75% is not licensed for use in the USA or in this country after reports of maternal mortality.[2] It causes more profound hypotension than 0.5% bupivacaine[3] while the latter provides adequate anaesthesia for Caesarean section The risk of hypotension with the more concentrated solution cannot therefore be justified. The addition of intrathecal morphine further compounds the problem. Morphine is relatively lipophobic and tends to remain in the cerebrospinal fluid rather than bind to spinal receptors and rostral spread has been reported frequently[4] with potential respiratory depression The authors used naloxone but did not state if this reversed the apnoea. Intrathecal diamorphine which is more lipophilic[5] would have been the better choice with less risk of cephalad spread. Another method which would have prolonged the block without the use of opioids is a combined spinal and extradural technique.

We have no doubt that this block spread above the thoracic segments, as the authors stated that bilateral sensory block to temperature was T2 to S5 Anaesthesia is always at least two dermatomes above the sensory level to cold.[6] Further, the authors did not state when the block was tested but a subarachnoid block often takes up to 20 min to achieve its maximum dermatomal height

No mention of fluid loading was given other than after delivery when an infusion of Syntocinon in saline was started. Presumably some type of fluid loading had been given, otherwise significant hypotension secondary to sympathetic block would have occurred with a drastically reduced venous return initiating the reflexes mentioned in the original report.

We find it highly significant that the arrest occurred after patient transfer. In clinical practice, repositioning patients, especially transferring them from theatre to ward bed, can cause sudden and profound hypotension, presumably because of a surge of local anaesthetic or opioid towards the cardiorespiratory centres, although theoretically, the agents should have "fixed" by this time.

While appreciating that the patient was not monitored at the time of collapse, would asystole not be the more likely rhythm if the pathogenesis was progressive bradycardia and hypotension in a previously healthy 31-yr-old? Ventricular fibrillation is suggestive of electrolyte abnormality with hypomagnesaemia possibly the culprit.

Sir,—Thank you for the opportunity to reply to Drs Burns and Clark. The use of 0.75% bupivacaine is not unusual in Canada, but we take the point that a more dense and prolonged sympathetic block may have contributed to the clinical scenario. However, hypotension was not a problem during operation. The patient received a preload of 1 litre of normal saline and the block was found to extend to T2, approximately 15 min after injection. Naloxone was given in the context of the arrest while IPPV was being administered, and therefore we cannot comment on its effect on respiratory depression.

We agree with Burns and Clark that the temporal relationship between the occurrence of cardiac arrest and transfer is highly significant. We feel, however, that the arrest was much more likely to have been caused by circulatory reflexes detailed in the report rather than "a surge of local anaesthetic or opioid toward the cardiorespiratory centres"

The presence of ventricular fibrillation does suggest an electrolyte abnormality; interestingly, Caplan and colleagues did not report on the presenting rhythm in their series of patients.

## Haemoglobin changes during anaesthesia

Sir,—In the description of their study of the inter-relationships between hypotension caused by extradural block, i.v. fluid therapy and haemoglobin concentration,[1] Drobin and Hahn have not mentioned one possible explanation for the association they observed between changes in arterial pressure and haemoglobin measurement. This explanation relates to the phenomenon termed "plasma skimming".[2] Axial streaming of red blood cells may imply that blood entering small proximal vessels is relatively plasma rich with the result that whole-body packed cell volume is lower than that of blood sampled from a distal vessel. The vasodilatation that accompanies extradural block may disturb this process and result in a decrease in haemoglobin concentration measured in peripheral blood samples. Decreases of the same order noted by Drobin and Hahn have been observed when hypotension is induced by both halothane and extradural block,[3] and by sodium nitroprusside,[4] yet occur with minimal fluid therapy. I am afraid that such observations call into question the use of change in haemoglobin concentration as an indicator of the amount of i.v. fluid that is "retained" in the circulation during fluid therapy.

2. Kelman GR. *Applied Cardiovascular Physiology*. London: Butterworths, 1971; 11.
3. Bond AG. Variability of haemoglobin concentration during anaesthesia. *British Journal of Anaesthesia* 1969; 41: 947–950.
4. Wildsmith JAW. *Induced Hypotension with Sodium Nitroprusside: Clinical Studies of Oxygen Transport.* MD Thesis. Edinburgh: University of Edinburgh, 1981; 60–66.

Sir,—I wish to thank Dr Wildsmith for alerting me to this possibility. In my mind, however, plasma skimming occurs at the microvascular level[1] and the concentration of any substance in a large arm vein corresponds to the concentration on the arterial side, the difference being explained by cumulation in tissue. In the past, isotope studies indicated that the peripheral packed cell volume is only 91% of whole-body packed cell volume and this ratio was found to be stable over a wide range of clinical situations, including anaemia, moderate blood loss and spinal anaesthesia.[2–4] This packed cell volume factor was later attributed to the methods of measuring blood volume, and the current view is that the capillary bed is the only location in the cardiovascular system where a packed cell volume different from that in the large vessels can exist.[5]

Arterial samples may be studied to further elucidate if venous blood samples accurately represent average haemodilution in large vessels. Arterial blood summarizes what happens in the whole body, whereas venous samples also reflect events in the tissue drained by the vessel (such as plasma skimming). In a patient series that I collected 10 yr ago, most of which is as yet unpublished, blood haemoglobin concentration was measured in blood collected simultaneously from the radial artery and a cubital vein during the onset of spinal ($n=10$) or extradural anaesthesia ($n=22$) before short urological operations. Samples were collected before any fluid was given, when half the volume load of Ringer's acetate 10 ml kg$^{-1}$ had been given, and when all fluid had been infused and anaesthesia was established. The result is shown in table 1 and indicates that blood haemoglobin concentrations in arterial and venous blood of the arm are similar in the resting state, during ongoing volume loading and after spinal or extradural anaesthesia has just been induced. The small gradient that develops is likely to reflect cumulation of fluid in the tissue between the artery and the vein, just as would be expected during fluid loading.

*Table 1* Mean (SD) blood haemoglobin (Hb) concentration in arterial (A) and venous (V) blood during induction of spinal and extradural anaesthesia in 32 patients. *Analysed without extreme outliers (+10 to 11 g litre$^{-1}$), one for each point in time

| | | Hb concn (g litre$^{-1}$) | |
|---|---|---|---|
| Time | | A−V mean | A−V difference* |
| 0 min | Before fluid loading | 137.4 (13.8) | 0.0 (2.9) |
| 20 min | 50% of fluid load (total 10 ml kg$^{-1}$) | 131.7 (15.1) | −0.2 (3.1) |
| 40–45 min | 100% of fluid load Anaesthesia induced | 126.7 (14.6) | −0.3 (2.1) |

The haemodilution reported by Dr Wildsmith to be associated with the use of hypotensive agents probably represents a shift of interstitial fluid to the plasma, or else that most of the concurrently infused fluid remains in the blood. The second possibility is correct, at least in the case of extradural-induced hypotension, as no haemodilution occurs in the absence of i.v fluid administration.[6]

## Unexpected difficulty in the lighted stylet-aided tracheal intubation via the laryngeal mask

Sir,—We reported that it was easy to pass a lighted stylet (Trachlight: Laerdal Medical Corporation, NY, USA) through the laryngeal mask into the trachea, and speculated that this stylet would facilitate blind tracheal intubation via the laryngeal mask.[1] We therefore planned a formal study in 40 patients to assess the efficacy of this technique.

After obtaining approval from the local research Ethics Committee and informed consent, we allocated patients randomly to one of two groups. In one group, tracheal intubation via the laryngeal mask was attempted with the use of the lighted stylet, whereas in the other group, it was attempted without the use of the stylet. The laryngeal mask was inserted and its position assessed using a fibreoptic bronchoscope A 6.0-mm Mallinckrodt reinforced tracheal tube, which is the largest size that can pass through the laryngeal mask and the longest (35 cm including the connector), was inserted with or without the lighted stylet through the laryngeal mask. Manipulation of the patient's head and neck or rotation of the tracheal tube was allowed only when there was difficulty in insertion of the tracheal tube Two attempts were allowed

We abandoned the study after 12 patients because, contrary to our speculation, it was almost always difficult to intubate the trachea via the laryngeal mask even when the lighted stylet was used. In patients in whom the lighted stylet was used, it was easy to intubate via the laryngeal mask in only one of six patients. In another patient, tracheal intubation succeeded at the second attempt after flexing the patient's neck. In the remaining four patients, it was impossible to intubate the trachea Without the use of the lighted stylet, tracheal intubation through the laryngeal mask succeeded in one of six patients at the first attempt and in another patient at the second attempt.

The success rate of blind tracheal intubation via the laryngeal mask may be very low, in particular when the position of the patient's head and neck is not manipulated [2,3] The Trachlight consists of a light wand and an inner malleable metal stylet When a curve is made to the stylet and the inner stylet is withdrawn for about 5–6 cm, the tip of the wand loses its rigidity and curves further anteriorly.[1] In the previous report,[1] this curve of the lighted wand allowed easy insertion of the lighted wand through the laryngeal mask into the trachea. In addition, if the lighted wand was impacted at the laryngeal inlet during insertion, it was possible to adjust the curve of the wand by withdrawing or re-inserting the inner metal stylet.

When the lighted wand was inserted as far as possible into the tracheal tube, the tip of the wand was positioned just short of the tip of the tube. When the metal stylet was withdrawn in this situation, the distal part of the wand and the tube curved only mildly, because of the rigidity and weight of the tube. In addition, when the wand and the tube were passed through the laryngeal mask, there was almost no movement of the distal part of the tracheal tube by withdrawal of the metal stylet because movements of the proximal part of the tube were restricted by the tube of the laryngeal mask. It is likely that this less effective control of the curve of the lighted wand led to a low success rate. Therefore, although it is possible that the success rate might be high if the Trachlight was longer than the current specification, the current Trachlight does not appear to be useful for tracheal intubation via the laryngeal mask.

# BOOK REVIEWS

*Postoperative Management of the Cardiac Surgical Patient.* J. P. Williams (editor). Published by Churchill Livingstone, New York. Pp. 435; indexed; illustrated. Price £60.00.

Twelve chapters describing aspects of clinical management of patients after cardiac surgery are preceded by four chapters on the pathophysiology of adult heart disease and one outlining the pathophysiology of cardiopulmonary bypass. Each chapter is written by different authors from the USA or Europe, but the editor has managed to sustain an even style throughout

As the initial section title suggests, the mechanisms of preoperative disease are emphasized to give an understanding of the treatment principles to adopt. Regurgitant and stenotic valvular heart disease, cardiomyopathies and transplantation immunology are described in separate chapters, but it seems odd that the pathophysiology of ischaemic heart disease, which provides the most frequent indication for cardiac surgery, should not receive equal attention Cardiopulmonary bypass is considered separately. The technique is described and followed by an account of its effects on body systems.

The latter four-fifths of the book deal with clinical management. Chapters are devoted to individual body systems, nutrition, infection, pain management, cardiovascular pharmacology and mechanical circulatory support. By far the largest chapter is devoted to transoesophageal echocardiography and cardiac critical care. Forty-four pages include 10 figures, eight plates and 315 references up to 1995, and express the opinions of a committed enthusiast.

The text reads well, is given clarity by distinct sub-headings and is complemented by line diagrams and tables. The clinical management chapters include details such as drug doses and ventilator settings. The prescriptive approach is concise and straightforward and can easily be adapted if required. Where there is controversy or lack of evidence, this is declared. The book is written by anaesthetists and would be an excellent handbook for others about to be confronted by the care of patients after cardiac surgery.

*Key Questions in Anaesthesia,* 2nd Edn. T. M. Craft and P. M. Upton. Published by Bios Scientific Publishers, Oxford. Pp. 126. Price £12 95.

This book contains 360 multiple-choice questions arranged as four practice papers of 90 questions each. The book is marketed as a practice examination aid for trainee anaesthetists preparing for postgraduate examinations in anaesthesia. The format of the questions follows that of the multiple-choice papers of the diploma examinations for the Fellowship of the Royal College of Anaesthetists. The questions themselves are based on the parent publication, *Key Topics in Anaesthesia,* by the same authors and publishing house. This in itself immediately causes problems as the questions in *Key Questions in Anaesthesia* test the reader's knowledge of *Key Topics in Anaesthesia* rather than the subject area as a whole.

One could imagine therefore that it is quite possible to have a good recall of the information in *Key Topics in Anaesthesia,* therefore score well in the *Key Questions* practice papers, but do considerably less well when questions are not orientated towards the one particular source of information. This problem is clearly compounded when information in the parent book is wrong or, more likely in such a short text, does not give a balanced view of the literature on any particular topic. The candidate for the final FRCA examination might also come unstuck in using *Key Questions in Anaesthesia* as the only source of practice MCQ questions because of recent changes in the examination itself. In the new format of the final FRCA examination MCQ paper there is more emphasis on the applied basic sciences and intensive therapy: this is not reflected in the balance of questions in each of the practice papers in *Key Questions in Anaesthesia.*

Nevertheless, such books as *Key Questions in Anaesthesia* are useful for the examination candidate and this particular book is perhaps as good as any that this reviewer has considered. The candidate is well advised to note that all such publications undergo considerably less rigorous vetting of questions and answers than questions used in actual examinations and therefore contain a higher proportion of questions that might be considered ambiguous However, it is perhaps one useful function of these books that such perceived ambiguity may stimulate the candidate to return to the literature to improve his own understanding of the particular area. So while I would recommend examination candidates to purchase this book I would not go so far as the authors, who state that there is no substitute for practice in achieving high marks for MCQ. Rather, I would advise that there is no substitute for knowledge and how that knowledge should be applied to clinical practice.

*Pain Treatment Centres at a Cross-roads: a Practical and Conceptual Reappraisal.* M. J. M. Cohen and J. M. Campbell (editors). Published by IASP, Seattle. Pp. 338; indexed. Price $69.00.

This book represents the distilled procedures of a meeting held in Baltimore, USA, in March 1995. It reflects the view that, after a quarter of a century, multi-disciplinary pain centres are at a cross-roads and at a time for reflection and assessment of current treatment approaches in chronic pain.

It includes contributions from many of the early pioneers in the pain movement together with some young thinkers in the field and, interestingly, from insurance industry representatives

It acknowledges that chronic pain has developed rather quickly with some treatment approaches being accepted as the gold standard, without critical review. The book's contributors agree that this "young" discipline is at a cross-roads in maturation and deserves careful examination of its concepts and treatments. Several issues are propelled by the book, including the concept of assessment of economic pressures forcing all health care providers to scrutinize the rationales and outcomes of their work, and the sense of a less than full consensus regarding the focus and treatment of pain management. Several questions are raised, including the evaluation and treatment offered in multi-disciplinary pain clinics, the availability of data to validate varying approaches, the question of cancer treatment within the multi-disciplinary pain centre and the problem of funding of health care in pain work, especially in the USA.

The book consists of focused presentations on varying lessons from the past quarter century in the multi-disciplinary pain clinic. It is divided into sections covering the spectrum of pain centre outcome of treatments, social and economic impact of pain and pain as a distinct speciality. It is wholly American, but undoubtedly relevant to pain practices in the UK. It acknowledges the "hidden back road" status of the pain clinic in the USA and the need for them to emerge as a "grand boulevard" in the health care system

## EDITORIAL I

# Extradural analgesia: does it affect progress and outcome in labour?

Extradural analgesia has been used to relieve labour pain in many obstetric units for more than two decades, yet controversy persists about its effect on progress and outcome in labour. There is general agreement that extradural analgesia increases the chances of a mother requiring an instrumental (forceps or Ventouse) delivery and prolongs the second stage of labour, although it is difficult to quantify this effect. Recently there has been debate on the influence of extradural analgesia on Caesarean section rates, with Thorp and colleagues suggesting its increasing use has played a significant role in the increasing rate of Caesarean section.[1] In the Cochrane Pregnancy and Childbirth Database (CPCD), Howell concluded that while extradural analgesia achieves better pain control than non-extradural analgesia, it does so at the expense of longer first and second stages, increased use of oxytocin, a two-fold increase in malrotation of the fetal head, a four-fold increase in instrumental deliveries and an unquantified increase in rate of Caesarean section for failure to progress.[2] If true, this would have a major impact on the information we should give parturients before siting an extradural catheter for analgesia in labour.

Millions of women have received the benefits of extradural analgesia in labour but few have participated in studies comparing extradural analgesia with other forms of pain relief.[3] Obstetric anaesthetists have been accused of "not living up to their responsibilities" by failing to undertake relevant randomized, controlled studies.[4] Several practical and ethical considerations make large studies difficult, if not impossible. Most women have firm views on the form of analgesia they prefer in labour. They might *change* their views during labour, but few are likely to consent to receive a pre-determined method of analgesia throughout labour. Would such a study be ethical given that extradurals give better pain relief than systemic opioids, which have depressant effects on the mother and fetus, and that women who have an extradural are less likely to receive a general anaesthetic with its associated problems if an emergency Caesarean section is required?

Two prospective, randomized, controlled studies comparing the impact of extradural with systemic opioid analgesia on the progress and outcome of labour have been completed; one in Denmark, the other in North America. Both studies were similar in size (112 and 93 patients) but their results differed. Philipsen and Jensen[5] found similar instrumental and Caesarean delivery rates in the two groups, although the Caesarean section rate was not significantly higher in the extradural group (17% and 11%, respectively). Extradural analgesia was discontinued at 8 cm cervical dilatation.[5] In contrast, Thorp and co-workers[1] demonstrated an 11-fold increase in Caesarean section rates in the extradural group (25% compared with 2.2%), the majority of which resulted from dystocia (16.7% *vs* 2.2%). Almost all women in the extradural group who required Caesarean delivery had received extradural analgesia early in labour (before 5 cm cervical dilatation). The authors concluded that women should be warned that they are more likely to require Caesarean delivery before receiving extradural analgesia and that extradural analgesia should be delayed until the cervix is more than 5 cm dilated.

The results of Thorp and co-workers' study have heavily influenced the conclusions drawn by Howell in the CPCD[2] and by the authors of another meta-analysis undertaken to investigate the impact of extradural analgesia on outcome of labour.[6] It is therefore appropriate to scrutinize the methodology of Thorp and colleagues. Criticisms have been numerous and many are fair. The authors of the paper were the clinicians responsible for deciding what constituted an arrest of first and second stage labour (dystocia) and investigators were not blinded to the analgesic method. There were no guidelines for management of labour or for oxytocin administration. Nevertheless, although this study has provoked much discussion and dissension, in the absence of other randomized, controlled studies it will continue be to cited as evidence that extradural analgesia in labour has a profound effect on labour.

Many non-randomized, uncontrolled studies have shown that extradural analgesia in labour is *associated* with longer labours and increased instrumental and Caesarean deliveries,[7 8] but whether this relationship is *causal* remains unclear; conversely it has been shown that increasing extradural rates do not necessarily result in increasing instrumental or Caesarean deliveries.[9] The downfall of many studies is their inevitable selection bias—women who request extradural pain relief in labour are more likely to be having longer, more painful or induced labours than those who do not and are also more likely to require operative delivery (instrumental or Caesarean).[10] What effect the extradural *per se* has on outcome is impossible to quantify.

What effect does obstetric management have on the outcome of labour? Giving oxytocin during labour and allowing a longer, second stage of labour promote normal vaginal delivery.[11] Adopting an active management of labour policy, with strict criteria for diagnosis of labour and oxytocin augmentation if required, can reduce instrumental and Caesarean deliveries. In one study of 1000 actively managed nulliparae, the Caesarean section rate was 5.6%, despite an extradural rate of 31%.[12] In a large observational study of 1250 primiparae, 67% of 568 women who received an extradural achieved a normal vaginal delivery when an active management of labour policy was used.[13] Women undergoing induced labours are more likely to require Caesarean or instrumental delivery, regardless of analgesic technique, and therefore induction rates affect operative delivery rates.[13 14] Induction, extradural, instrumental and Caesarean delivery rates vary greatly between hospitals and between individual clinicians; there are many factors other than extradural rates which contribute to the outcome of labour.[15]

Does modification of anaesthetic management influence obstetric outcome? Stopping extradural analgesia before the second stage promotes normal delivery, although at the expense of increased pain, which is unlikely to be popular.[16] In contrast with Thorp's data, Chestnut and colleagues have clearly demonstrated that early rather than late extradural placement does *not* increase operative deliveries.[14 17] In 1981, Thorburn and Moir, in a study of 517 women allocated randomly to receive either 0.25% or 0.5% extradural bupivacaine, showed that concentrated local anaesthetic solutions increased forceps delivery rates.[18] Many studies have aimed to minimize motor block by using low-dose bupivacaine–opioid mixtures which provide analgesia comparable with stronger bupivacaine but reduce total bupivacaine dose and its associated motor block. Two studies have shown that such combinations may reduce operative deliveries. Vertommen and colleagues' study of 695 women receiving extradural analgesia in labour showed that the addition of a lipophilic opioid (sufentanil) to 0.125% bupivacaine reduced bupivacaine requirements and the incidence of instrumental deliveries from 36 to 24%.[19] In a smaller UK study of 85 primiparous women, those who received low-dose bupivacaine and fentanyl were more likely to have a normal delivery than those receiving 0.25% bupivacaine.[20] It would appear that modification of anaesthetic practice may promote normal delivery but it would be fair to say that this remains controversial and many studies have failed to confirm these conclusions.

What remains unclear is *how* extradurals modify labour. In *second stage* labour there is evidence that extradural analgesia attenuates endogenous oxytocin production (Ferguson's reflex)[21] and reduces uterine contractility.[22] It is assumed that the motor block associated with extradural analgesia causes relaxation of the pelvic floor, predisposing to malrotation of the fetal head and reduces maternal effort during pushing. As regards *first stage* labour, extradurals do not appear to reduce uterine contractility, although cervical dilatation may be slower.[23]

Many factors can modify uterine contractility.[24] In a recent issue of the journal, Cheek and co-workers,[25] in a randomized, controlled study of 34 women in spontaneous labour, showed that administration of 1000 ml of normal saline fluid load before insertion of an extradural decreased uterine activity for 10–20 min. A smaller 500 ml load did not have a significant effect. Subsequent institution of an extradural block did not affect uterine activity. It was not apparent that the transient reduction in activity modified the overall progress of labour but it is important that obstetric anaesthetists avoid factors which may modify uterine activity. Thorp and colleagues fail to provide information on fluid preload before extradural insertion[1] but it is common practice in North America to fluid load with at least 1000 ml of fluid.

Does the effect of a fluid load on uterine activity affect European anaesthetists? While giving an i.v. fluid load before extradural *analgesia* is not routine practice in the UK, it is before regional *anaesthesia* for Caesarean section, when a profound, high sensory block is accompanied by widespread sympathetic block. This practice has been questioned recently by Jackson, Reid and Thorburn who showed that a 1-litre fluid load failed to reduce the incidence or severity of hypotension associated with subarachnoid block for Caesarean section.[26] It is therefore unnecessary, and possibly detrimental to uterine activity, to fluid load before extradural analgesia for labour.

In summary, while it is impossible to exonerate extradural analgesia in labour from modifying the course of labour, the suggestion that extradurals are important contributors to increasing Caesarean section rates should be repudiated. The knee jerk reaction of obstetricians to blame anaesthetists for obstetric interventions should be resisted. Any impact of extradurals on outcome of labour is overshadowed by that of obstetric practice. Nevertheless, it is important that obstetric anaesthetists continue the search for an extradural technique which minimizes side effects, introduce such techniques if they are shown to be beneficial and encourage obstetricians to adopt policies which promote normal deliveries. For the foreseeable future extradural services will be essential to modern obstetric practice; extradurals can provide pain relief superior to all other forms currently available, and although many women in the UK may not *plan* to use it, it is clear that many request it during labour and are disappointed if it is not available. Labour can be extremely painful for many women. They are entitled to receive extradural analgesia if they wish without being exposed to unsubstantiated scare stories about its side effects.

EDITORIAL II

# Recent advances in prophylaxis against deep vein thrombosis

Deep vein thrombosis (DVT) is a condition which presents a diagnostic and therapeutic challenge to all clinicians directly involved in patient care. The spectrum of acute disease ranges from asymptomatic thrombosis (typically affecting distal, calf veins) discovered incidentally at autopsy or during screening procedures, through to the classic swollen, red, painful leg, to the potentially fatal complication of pulmonary embolism. In the long term DVT may lead to the troublesome post-thrombotic syndrome of persistent swelling, pain, pigmentation and ulceration, and this can affect up to 25% of patients with DVT.[1 2] It is difficult to determine a value representing the true incidence of this disease as it is well documented that many DVT are not detected clinically[3–6]; however, the fact that it is a significant problem is well recognized. A study in 1988 in the UK found that 0.9% of all admissions to hospital suffered fatal pulmonary embolism as a result of DVT,[4] and the incidence of DVT in surgical patients is 10–80%, depending on the type of surgery and individual patient risk factors.[7–10]

As always, prevention is better than cure, and apart from the obvious benefit to patients, prophylactic measures against DVT are cost effective through reduction in fatal complications and treatment requirements.[10 11] It has been estimated in the USA that widespread use of prophylactic measures in surgery would save $60 per operated patient.[12] Over the course of the past 5–10 yr there has been an increasing awareness of the importance of DVT prophylaxis, stimulated in particular in the UK by the reports of the THRIFT (Thromboembolic Risk Factors) Consensus Group and the National Confidential Enquiry into Perioperative Deaths 1992,[9 13] and a great deal of effort has been put into developing safe and effective methods of prophylaxis.

There are already several different, effective methods of DVT prophylaxis available, which are traditionally divided into two categories: physical and pharmacological methods. Graduated compression stockings are the most popular physical method, with intermittent compression devices being more cumbersome to use and less well tolerated. Low-dose heparin is the mainstay of pharmacological prophylaxis, with a wide variety of other drugs being used with varying degrees of success (warfarin, aspirin, dextran, dihydroergotamine). In the face of existing, effective measures, the recent advances in this field have been refinements of tried and tested methods, and they are described here.

## Physical methods

### INTERMITTENT COMPRESSION DEVICES

Intermittent pneumatic compression (IPC) of the lower limbs has been used over the past 30 yr, and while the original compression boots were uncomfortable and tolerated poorly[14] modern designs with sequential pressure application have been more widely accepted. IPC works both by eliminating venous stasis with generation of pulsatile blood flow (simulating the effect of the "muscle pump") and by stimulating fibrinolysis.[15 16] The most recent addition to the range of devices available is the arterial–venous impulse foot pump which is applied to the patient's foot and provides compression to the plantar venous complex. This device has been used mainly in orthopaedic patients undergoing knee and hip surgery where it has significantly reduced the incidence of DVT.[17–20] Its advantages include good patient tolerability compared with conventional IPC boots enabling it to be used after operation until the patient is mobile, and avoidance of the haemorrhagic complications associated with other methods of prophylaxis. So far it has been evaluated only in knee and hip surgery, and it may not be as effective as existing IPC devices.

## Pharmacological methods

### LOW MOLECULAR WEIGHT HEPARIN

Heparin exerts an antithrombotic effect by binding to, and accelerating the activity of, two cofactors; antithrombin III and heparin cofactor II. The rationale behind the use of low-dose heparin as prophylaxis is that only small amounts of the drug are required to inhibit the clotting cascade in its early stages, before coagulation is established, and conventional, unfractionated heparin has been used in this way since the 1960s.[21] A meta-analysis of more than 70 randomized, placebo-controlled studies in 1988 showed that the incidence of DVT was reduced by 66% and the incidence of pulmonary embolism reduced by 50%[10] with unfractionated heparin administered subcutaneously in low dose (5000 u. 8 or 12 hourly).

Recent interest in heparin prophylaxis has centred on low molecular weight heparins, so called because their range of molecular weight is 2000–8000 Da, compared with 5000–30 000 Da for unfractionated heparin.[7] Low molecular weight heparins have several differences from unfractionated heparin, apart from molecular weight, which help to explain their therapeutic advantages. Low molecular weight heparins have a much greater anti-Xa than anti-IIa activity, which theoretically makes them more effective at preventing thrombin formation than unfractionated heparin with an equal anti-Xa and anti-IIa ratio, and *in vivo* activity certainly shows good correlation with anti-Xa activity.[22 23] Low molecular weight heparins have a bioavailability approaching 100%, compared with 30% for unfractionated heparin, and a half-life after subcutaneous injection of 3–5 h, enabling a single dose to provide effective anti-thrombotic activity for 24 h.[22 24] The smaller charge density and chain length of low molecular weight heparins decrease their binding to several proteins (platelet factor 4, lipoproteins, fibronectin and protamine), endothelial cells, macrophages and platelets.

Low molecular weight heparins are at least as effective as unfractionated heparin at preventing DVT in both general and orthopaedic surgery, and the incidence of bleeding episodes is not significantly different between the two in most studies so far.[22 25–27] The one area where low molecular weight heparins show an undisputed advantage is that of convenience and patient acceptability; the once-daily dose is easier for nurses and patients, and there is significantly less bruising at injection sites.[25]

### ORGARAN

Orgaran is a low molecular weight heparinoid consisting of a mixture of heparan sulphate, dermatan sulphate and chondroitin sulphate, chemically distinct from heparin. Although not in widespread use it has been evaluated in several studies of patients at high risk of DVT, where it has been shown to be effective and comparable with low-dose heparin.[28]

## Guidelines

DVT prophylaxis is effective only if it is given to the correct patients for the correct period of time, and the development of hospital guidelines to ensure that this happens is probably as important as any therapeutic advance. A guidelines should enable classification of patients admitted to hospital as to their degree of risk, and the recent recommendation of the European Consensus Group can be summarized as follows:

- Low-risk patients:
  - <40 yr old without additional risk factors.
  - Minor surgery (<30 min).
- Moderate-risk patients
  - >40 yr old.
  - Oral contraceptive medication.
  - Major surgery (>30 min).
  - Immobilized medical patients with active disease.
- High-risk patients
  - Previous DVT/PE.
  - Major surgery for malignant disease.
  - Orthopaedic surgery to lower limbs.
  - Stroke, congestive cardiac failure and acute myocardial infarction.

(Adapted from the European Consensus Statement [29]).

Low-risk patients may not benefit from prophylactic measures, but all moderate- and high-risk patients should be offered prophylaxis as a matter of routine. The preferred type of prophylaxis varies from hospital to hospital, and even between hospital departments, the most important factor being that patients are assessed correctly for risk and the relevant local policy then implemented.

## Surgical specialties

Different specialties have particular considerations which influence the choice of prophylaxis.

### OBSTETRICS AND GYNAECOLOGY

Young women receiving the oral contraceptive pill (OCP) are in at least the moderate-risk group and should discontinue this 6 weeks before elective surgery, or should be given subcutaneous heparin and/or compression stockings if admitted as an emergency. Hormone replacement therapy (HRT) has not been shown to increase the risk of thromboembolic disease, but patients receiving HRT are aged more than 40 yr of age and should therefore qualify for prophylaxis. Some clinicians would advise patients to discontinue HRT 6 weeks before elective surgery as for the OCP.

### UROLOGY

Because of the endoscopic nature of most urological surgery, haemostasis is not as easily secured as during open surgery. Consequently, any drugs which predispose to bleeding are avoided as far as is possible, aspirin in particular being stopped 2 weeks before elective transurethral surgery. Heparin is avoided as a choice for prophylaxis, and mechanical methods are preferred.

### ENT

Major head and neck surgery is performed on a part of the body renowned for vascularity, and therefore mechanical prophylaxis is preferred rather than pharmacological methods with their increased risk of postoperative bleeding.

### NEUROSURGERY

These patients have a similar risk of DVT as general surgical patients,[24] but the consequences of an intracranial bleed are so severe that, as with ENT, mechanical methods are preferred.[14 30]

## Summary

The major development in DVT prophylaxis in recent years has been the introduction of low molecular weight heparins. Their main improvement compared with unfractionated heparin is in the convenience of a once daily dosage, but they have not yet convincingly been shown to be more effective or safer.[22 23] A-V impulse boots may have an impact on knee and hip surgery but still face problems with patient acceptability. Probably the best way to ensure that more DVT are prevented is by clinicians maintaining a high level of awareness of the risk, and developing, and adhering to, local guidelines.

## Thermoregulation in critical illness

Mammals owe their success, in part, to the ability to maintain their central body or core temperature within narrow well defined limits. The survival value of such a facility (being able to carry out high rates of muscular, neuronal and cellular work independently of environmental temperature) is obvious.[1] Body temperature is "set" within the central nervous system. The areas associated with temperature control lie in the hypothalamus and preoptic region. There are two distinct groups of neurones concerned with temperature control, one promotes heat loss, the other heat production and conservation. The principal synaptic mediators are noradrenaline, associated with heat loss, and 5-hydroxytryptamine, associated with conservation of heat. Acetylcholine is associated with the mechanisms whereby heat is lost or conserved (sweating, shivering, etc).

Heat is produced in humans for "basal" requirements (maintenance of cell membrane potentials, the energy cost of the beating heart, of breathing, etc.), absorption and assimilation of food, and muscular activity. The traditional view has been that non-shivering thermogenesis in adult humans, as mediated by brown adipose tissue and seen in hibernating animals and in the human neonate, does not exist, although the subject has been highly controversial.[3–5] Humans defend their body temperature from a cold stimulus mainly by behavioural means—seeking shelter, lighting a fire and putting on more clothes. Physiological mechanisms include peripheral vasoconstriction and perhaps increasing food intake, but the only means of significantly raising heat output is by muscle contraction—exercise, shivering and an increase in muscle tone. Acclimatization to cold is thought to be limited to an increase in the efficiency of the peripheral vasoconstrictor mechanisms.[1] Acclimatization to heat, in contrast, is well documented and accompanied by increased sweat rates, an increase in blood volume and a decrease in the $Na^+$ and $Cl^-$ content of sweat and urine.[1] The range of body temperature within which the individual can survive is between approximately 25 °C (representing a heat debt of approximately 700 kcal) and 42 °C (representing a heat gain of approximately 360 kcal). The limits within which homeothermy can be maintained and the organism function effectively are from 35–36 to 41 °C.[1] Both trauma and infection alter the temperature at which the body "sets" its internal environment and in general, temparature is increased.[6] In addition to external pyrogens the mediators of this change in temperature control are the various cytokines such as interleukin-1[7] and tumour necrosis factor[8] and they act within the hypothalamus, promoting prostaglandin synthesis.

Over the past 20 yr we have become increasingly aware that during surgery patients' temperatures tend to decrease, that this is worse in the very young, in the very old and in surgery that is prolonged.[9] Postoperative recovery from intraoperative hypothermia is associated with severe metabolic disturbances in terms of counter-regulatory hormone secretion[10] and increases in energy expenditure (shivering) with its associated cardiovascular stress[11] and potential for hypoxaemia.[12] More long-term problems are disturbances in protein metabolism[13] and loss of lean tissue,[14] but on recovery of consciousness the individual is able to respond.[15] On awakening, muscle tone and metabolic rate increase and body temperature increases up to or exceeds preoperative values reasonably quickly.[15,16]

In the (adult) intensive care unit hypothermia is not generally a problem, despite patients being nursed virtually naked, under relatively insubstantial coverings, frequently bed-bathed, kept sedated to varying degrees, sometimes paralysed completely and at several degrees below that usually considered as thermoneutral. A recently published textbook on intensive care[17] mentions disturbances in temperature control only as a specific injury or secondary to a specific pathology, not as a particular problem of medical or nursing care.[17]

In acute and critical illness however, hyperthermia, or fever, can be a problem. Even simple trauma or surgery, as part of the acute phase response, results in an increase in body temperature.[6,18] With infection, pyrexia is usually quite marked. This may have positive[19] or negative[20] effects on the body's ability to respond to the invading organism, but it can be uncomfortable for the patient and alarming for his or her attendants. The intuitive response is to take steps to reduce a high fever, normally with antipyretic agents, or in more severe circumstances by "tepid sponging".[21,22] The usual concern about applying ice cold water to the pyrexial patient is the danger of inducing peripheral vasoconstriction, reducing peripheral heat loss and making the pyrexia worse.[1,23]

In this issue of the journal, Poblette and colleagues describe the results of manoeuvres designed to reduce pyrexia in sedated patients undergoing artificial ventilation.[24] Two centrally acting antipyretic agents were tried; they did nothing, but overall surface cooling with cloths soaked in iced water produced a rapid and effective decline in body temperature of 2 °C, a decrease in heart rate and a decrease in oxygen consumption of 12%. Perhaps surprisingly temperature remained reduced and there was no evidence of shivering. The antipyretics are thought to work by inhibiting prostaglandin synthesis in the brain.[25] Whatever the mechanisms, they did not work in this instance, but ice-cold water did. One might have expected such a severe peripheral stimulus to have elicited the responses to protect body temperature discussed above—peripheral vasoconstriction and an increase in muscle tone. In the one patient who was not sedated, body temperature increased with an increase in energy expenditure of 100%, but with no visible signs of shivering.

None of the patients was paralysed. Apart from the individual noted, all were sedated with morphine and midazolam, but we are given no indication of their level of consciousness. The reduction in energy expenditure of 6% $°C^{-1}$ is comparable with previous values published for this type of patient[26 27] and contrasts with that of 13% $°C^{-1}$ usually quoted for normal, conscious individuals.[28]

The decrease in central temperature in response to the treatment with iced water implies an inability to defend body temperature adequately in these particular circumstances. The most likely causes are the drugs used to maintain sedation (morphine and midazolam). It is not entirely possible to exclude the effects of the illness itself, but anaesthetic and analgesic drugs are known to inhibit thermoregulatory responses (the inhalation agents being the worst), both by central and peripheral mechanisms.[29–32] It appears that this allows us to manipulate body temperature in severely ill patients to a degree, and in a fashion, that in the unsedated individual would not be possible. In view of the rapidity with which postoperative patients regain normal temperature however one cannot help but wonder if the ability to defend or regain core temperature is related also to level of consciousness.

CLINICAL INVESTIGATIONS

# Metabolic effects of i.v. propacetamol, metamizol or external cooling in critically ill febrile sedated patients

B. POBLETE, J.-A. ROMAND, C. PICHARD, P. KÖNIG AND P. M. SUTER

## Summary

We have measured the metabolic response to sequential administration of propacetamol, metamizol and/or external cooling in 20 febrile patients under sedation and analgesia and during mechanical ventilation. There was no change in temperature (T°) after propacetamol therapy, whereas after metamizol only a small decrease was noted (from 38.9 (SEM 0.2) to 38.5 (0.3) °C; $P=0.02$). External cooling produced a significant decrease in T° (39.1 (0.2) to 37.1 (0.2) °C; $P<0.0001$) accompanied by a decrease in energy expenditure (EE) (2034 (73) to 1791 (88) kcal day$^{-1}$; $P<0.004$). Heart rate and minute ventilation decreased significantly in parallel. There were no other changes in haemodynamics or pulmonary gas exchanges. We conclude that propacetamol and metamizol did not produce a clinically significant decrease in T° in febrile ICU patients whereas external cooling decreased both T° and EE. The parallel decrease in body temperature and EE seemed to be related to opioid administration or sedation, or both. (*Br. J. Anaesth.* 1997; **78**: 123–127).

**Key words**
Temperature, monitoring. Temperature, metabolism Measurement techniques, calorimetry Intensive care.

Fever in critically ill patients is related frequently to either the systemic inflammatory response syndrome (SIRS) or infection. Usually fever is treated with antipyretic drugs, often paracetamol or metamizol. External cooling by different methods, such as sponging the body surface with ice-cooled water, is also used.[1] Even if reducing fever is still controversial from an immunological point of view, there is little doubt that patient comfort and metabolic demand can be improved by this procedure.[2] Indeed, a previous study in critically ill patients demonstrated diminished oxygen consumption related to decreased body temperature improving the oxygen demand–delivery ratio.[3] However, body cooling in healthy humans results in shivering which increases energy expenditure (EE).

The aim of this study was to measure EE as an integrated indicator of body metabolic activity after reduction in temperature. Our hypothesis was that external cooling may induce an increase in EE, in contrast with drugs which, by resetting the thermoregulatory set point, decrease EE. Therefore, we designed a prospective, unblinded, crossover study to evaluate the respective effects of centrally acting drugs (propacetamol or metamizol) or external physical cooling in febrile ICU patients.

## Patients and methods

The study was approved by the Ethics Committee of our institution. The requirement for informed consent was waived by the committee who judged that the therapies were applied independently by the attending physician and were accepted in clinical practice, and no invasive measurements were made. We studied 20 patients undergoing mechanical ventilation via a tracheal tube, with a rectal temperature greater than 38.5 °C and in whom the physician in charge wished to decrease fever. No patient had an inspired oxygen fraction greater than 0.6, a pneumothorax or a broncho-pleural fistula. Patients' lungs were ventilated with a Veolar-Hamilton (Hamilton Bonaduz, Switzerland) or Engström-Erica ventilator (Engström, Bromma, Sweden). Ventilatory settings, adjusted to obtain normal arterial blood-gas tensions, were maintained constant during the study. No patient received a caloric intake exceeding the measured EE at baseline. Analgesia and sedation were adjusted to obtain clinical comfort of the patient, as judged by nurses and physicians, by a continuous and constant infusion of morphine 2–6 mg h$^{-1}$ and midazolam 2–10 mg h$^{-1}$ to obtain a sedation level of 3–4, according to the score of Ramsay and colleagues.[4] Patients were kept supine during the study.

The following variables were monitored continuously: rectal temperature, heart rate and arterial pressure, ventilatory frequency, tidal volume; inspired and expired minute ventilation were recorded from the ventilators. Oxygen consumption ($\dot{V}o_2$) and carbon dioxide production ($\dot{V}co_2$) were also measured continuously by indirect calorimetry

(Deltatrac, Datex Instrumentation Corp., Helsinki, Finland) and EE was recorded and calculated using a modified De Weir formula. Shivering was assessed continuously by the nurse and investigators. Arterial blood-gas tensions were measured intermittently with Stat profile (Nova Biomedical, Boston, MA, USA).

### TREATMENT DESIGN

The aim of the study was to measure the metabolic response to reduction in temperature induced by different therapeutic means. There was no randomization at enrolment of patients or of therapy sequence chosen, because the choice of treatment was decided independently by the physician in charge of the patient and not by the investigator. Three different antipyretic therapies used currently in our unit were prescribed: i.v. bolus administration of propacetamol 1000 mg or metamizol 500 mg, or external cooling with cloths plunged into iced water and placed on most of the body surface. Cloths were changed every 15–30 min. In case of failure of the first treatment, a second and, if necessary, a third treatment were given until the desired temperature was obtained. Treatment was considered to have failed if temperature either increased or decreased <1 °C in the 60 min after administration of therapy.

### METABOLIC MEASUREMENTS AND CALIBRATION

Before and after measurements, the Deltatrac metabolic monitor was calibrated for room air according to the manufacturer's instructions. Calibration for atmospheric pressure and a standard gas blend containing 95% oxygen and 5% carbon dioxide was also carried out before measurements began. The Deltatrac metabolic monitor is an open system connected to the ventilator which collects expired air from the ventilator outlet port and measures carbon dioxide and oxygen fractions in inspired, mixed expired and diluted expired gas. The carbon dioxide fractions are measured with an infrared carbon dioxide sensor (CX 104, Datex Instrumentation Corp, Helsinki, Finland); the difference between the inspired and expired oxygen fractions is measured with a differential paramagnetic oxygen sensor (OM 101, Datex Instrumentation Corp, Helsinki, Finland). $\dot{V}_{CO_2}$ is calculated as the product of the carbon dioxide fraction in the diluted expiratory flow and a constant flow of 45 litre $min^{-1}$. $\dot{V}_{O_2}$ is calculated as $\dot{V}_{CO_2}$ divided by the respiratory quotient (RQ) where $RQ=(1-F_{IO_2})/(F_{IO_2}-F_{E'O_2})/F_{E'CO_2}]-F_{IO_2}$.[5] A baseline steady state (baseline 0) was established for each patient. Steady state was defined as a stable $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$ and EE (<10% changes from preceding values) during at least 10 min. Thereafter, the first antipyretic therapy was given.

Before changing to alternative treatment, all variables were recorded and assumed as the new baselines (baseline 1 or 2) for the subsequent therapeutic manoeuvre. The final measurement was recorded under metabolic steady state conditions as defined above.

### STATISTICAL ANALYSIS

Data were compared between different therapies (propacetamol, metamizol and external cooling) using one-way analysis of variance; when a significant difference was seen, the Tukey–Kramer multiple comparisons test was used. The paired *t* test was also used to compare treatment effects with their respective baseline conditions. GraphPad InStat 2.0 (GraphPad Software, San Diego, CA, USA) was used for statistical analysis. Data are expressed as mean (SEM).

## Results

We studied 20 patients (four females), mean age 47 (range 17–79) yr. Admission diagnosis, treatment

outcome and Apache II score are listed in table 1. At the end of the study, data from one patient (No. 17) were excluded from the final analysis. This patient suffered from rhabdomyolysis and hypoxic encephalopathy and therefore received no sedation/analgesia to allow continuous neurological evaluation/surveillance. He developed an important increase in EE during external cooling (>100%) without visible signs of shivering.

Synchronized intermittent mandatory ventilation (SIMV) was used in eight patients; in 10 patients ventilation comprised pressure support mode (PS) and positive end-expiratory pressure (PEEP), and in one patient volume controlled mode was used. Only one patient (No. 7) received a neuromuscular blocking agent for controlled hyperventilation. In parallel with the decrease in body temperature, minute ventilation decreased significantly (from 14.7 (1) to 13.1 (0.9) litre $\text{min}^{-1}$; $P=0.02$), but arterial oxygen saturation ($Sa_{\text{O}_2}$ from 94 (1) % to 95 (1) %), the quotient relating arterial partial pressure of oxygen and inspired oxygen fraction ($Pa_{\text{O}_2}/FI_{\text{O}_2}$ from 203 (19) mm Hg to 190 (17) mm Hg) and arterial pH (from 7.39 (0.01) to 7.39 (0.01)) did not change significantly. Patients continuously received either enteral ($n=7$) or parenteral ($n=4$) nutrition, or a combination of both ($n=3$), or no nutritional support ($n=5$).

## METABOLIC RESULTS

Treatment sequence is shown in table 2. Fourteen patients who first received i.v. drugs needed more than one treatment to decrease body temperature. In contrast, in five of six patients external cooling significantly decreased temperature. In four patients body temperature was controlled either by metamizol ($n=2$) or by a combination of paracetamol and external cooling. Temperature, haemodynamic and metabolic variables at baseline and after treatment are shown in table 3. During baseline measurements, mean percentage of random variation was 1.8 (6.7) % (median 0.0%; lower and upper 95% confidence intervals −2.3% and +5.8%, respectively). There were no differences between baselines 0, 1 and 2 for all study variables. Temperature did not change significantly after administration of propacetamol. Metamizol resulted in a statistically significant but clinically irrelevant decrease in temperature from 38.9 (0.2) to 38.5 (0.3) °C ($P=0.02$). In contrast, application of external cooling decreased temperature from 39.1 (0.2) to 37.1 (0.2) °C ($P<0.0001$). There were no clinical signs of shivering with either therapy.

Treatment with metamizol or external cooling decreased heart rate significantly ($P=0.0043$ and $P<0.0001$, respectively), but no significant change was observed after administration of propacetamol ($P=0.14$).

Five patients received vasopressor infusions to maintain adequate systemic arterial pressure, and in three (Nos 6, 7 and 15) the dose of these agents was reduced during the study. In two other patients (Nos 9 and 20) no change in noradrenaline infusion was made. Table 3 demonstrates that excluding the three patients in whom the catecholamine dose was modified did not significantly influence the metabolic changes induced by the different treatments.

Administration of propacetamol and metamizol did not significantly change mean values of EE ($P=0.35$ and $P=0.41$, respectively). However,

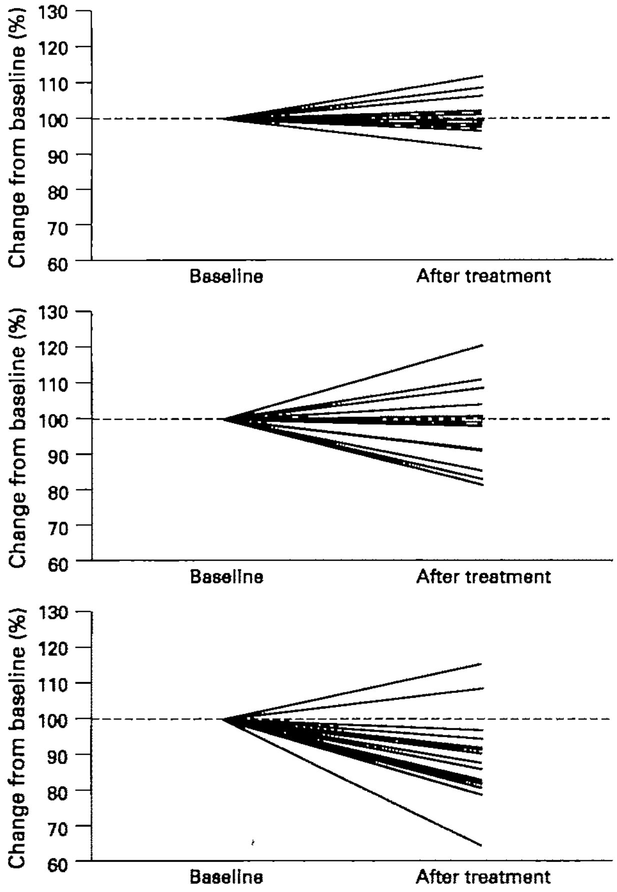

*Figure 1* Individual variations in energy expenditure. Post-treatment values for propacetamol (top), metamizol (middle) and external cooling (bottom) are expressed as percentage of baseline.

external cooling decreased EE significantly from 2034 (73) to 1791 88 kcal day$^{-1}$ ($P$=0.004). Metabolic variations calculated as percentage changes from baseline are summarized in table 3. Mean $\dot{V}\mathrm{O}_2$ decreased by 12.6 (3.3) % and $\dot{V}\mathrm{CO}_2$ by 10.9 (4.3) % during external cooling.

Figure 1 shows individual percentage variation in EE from baseline for treatment with propacetamol, metamizol and external cooling. There was wide variability among patients' responses to the treatments with propacetamol and metamizol. However, in patients treated with external cooling, EE decreased by 6.1–36% from baseline in 17 patients; in two patients (Nos 14 and 13) EE increased by 7.9% and 15.3%, respectively.

## Discussion

Twenty febrile ICU patients were prospectively enrolled to compare the respective effects of antipyretic drugs (propacetamol or metamizol) or physical (external cooling) therapies on body temperature and metabolic variables using indirect calorimetry. The major finding was a decrease in EE related to a decrease in body temperature in patients treated by external cooling, whereas treatment by propacetamol or metamizol did not induce a clinically relevant decrease in body temperature.

External cooling is thought to have no effect on the thermoregulatory setpoint.[6–8] Furthermore, it is generally admitted that a physiological response to cold stress is shivering[2] to maintain core temperature. Therefore, in response to external cooling, EE could either vary independently of T° or increase with diminution of body temperature. Our findings did not confirm our hypothesis that external cooling did not affect or increase metabolic rate. The association between a decrease in both body temperature and EE could be because of the absence of a compensatory homeostatic response. This physiological response was most probably blunted by morphine or sedation with midazolam, or both.[9–12] This possibility is fully supported by the fact that patient No. 17 was excluded because he developed a shivering-equivalent reaction with increased EE while not receiving opioids as he required close neurological surveillance. This observation further supports our hypothesis that in the absence of sedation or analgesia, increased EE is expected during external cooling. A similar observation was also reported by Manthous and colleagues.[3] Indeed, shivering is suppressed by general anaesthetics, centrally acting agents such as clonidine and especially by opioids such as pethidine, morphine and fentanyl.[10]

In clinical practice, although controversial, antipyretic therapy is often prescribed to combat temperatures greater than 38.5 °C. Indeed, fever complements the host immunological defence against invasion by micro-organisms. However, when a decrease in body temperature seems clinically important then paracetamol or metamizol are often prescribed. Drug-induced antipyrexia is preferred because it is easier than application of iced sponges and has proved to be efficient in paediatric studies.[13–15] Our study has demonstrated that external cooling, under sedation–analgesia conditions, is a valuable means of decreasing temperature with a concomitant decrease in oxygen consumption. The 12% decrease in oxygen consumption in externally cooled patients matched previously published data reporting a 5–7% change in metabolism per 1 °C change in temperature.[16] Thus even though the benefit of decreasing fever is debatable, decreasing EE and oxygen consumption may be clinically relevant in patients lacking coronary artery oxygen delivery reserve experiencing a septic episode or severely hypoxaemic.

The limitations of the study are that first, the treatment sequence was not randomized, but the physician in charge of the patient was proposed a random sequence of treatment by the investigators and the final decision left to him. This procedure may have introduced possible bias into the study. Second, to minimize spontaneous changes in body temperature not related to the treatment procedure, there was no washout period between i.v. drug administrations, which may have resulted in some overlapping between treatments. However, from a clinical viewpoint, if 2 h after administration of treatment no clinically relevant effect is observed, then therapy is usually considered to have failed, leading to administration of another form of therapy. Finally, these effects were not caused by variations in pH, nutrition or ventilation, or by changes in sedation or analgesia (tables 2, 3).

We conclude that propacetamol and metamizol administration had no observable effect on fever in critically ill patients under analgesia and sedation, whereas external cooling efficiently decreased body temperature and metabolic demands.

# Hormonal responses and cardiac filling pressures in head-up or head-down position and pneumoperitoneum in patients undergoing operative laparoscopy

E. A. HIRVONEN, L. S. NUUTINEN AND O. VUOLTEENAHO

## Summary

In order to determine if there are differences in stress responses, as reflected in neuroendocrine activation, we have compared data from two groups of patients undergoing laparoscopic surgery either in the head-up position for cholecystectomy or in the head-down position for hysterectomy. Arterial blood samples were obtained for measurement of serum concentrations of cortisol, catecholamines, renin activity and atrial natriuretic peptide (measured as *N*-terminal peptide of proANP), and haemodynamic data (pulmonary capillary wedge pressure, PCWP) were collected at the following times: in awake patients, supine at rest (baseline); in awake patients in the position used during surgery; during laparoscopy; and 2 h after surgery. The same anaesthetic technique and normocapnic mechanical ventilation were used in both groups. There were no significant differences between groups in cortisol or adrenaline concentrations, or in renin activity. There was, however, a threefold increase in cortisol towards the recovery period in both groups. Noradrenaline concentrations increased more in the head-up group suggesting increased sympathetic nervous activity. In awake patients, plasma NT-proANP concentrations were significantly higher in the head-down tilt compared with the head-up position, and NT-proANP correlated well with PCWP. During pneumoperitoneum, however, NT-proANP concentrations remained low in spite of increased PCWP suggesting that inflation of the abdomen interferes with venous return. In conclusion, abdominal surgical laparoscopy in both the head-up and head-down positions caused marked activation of neuroendocrine responses. The two surgical positions, however, differed in their effect on the circulation. In awake patients, head-down tilt was associated with increased concentrations of plasma NT-proANP, indicating increased venous return and atrial stretch. (*Br. J. Anaesth.* 1997; **78**: 128–133)

**Key words**
Surgery, hormonal response. Hormones, adrenal. Hormones, atrial natriuretic peptide. Position, effects. Surgery, laparoscopy. Cardiovascular system, effects.

Nociceptive surgical stimulation is accompanied by activation of the hypothalamic–pituitary–adrenal (HPA) axis and by increased activity of the sympathetic nervous system, which is generally referred to as the stress response to surgery. It is believed commonly that the magnitude of the response is related directly to the size of the wound.[1] On the basis of clinical experience, minimal-access techniques in abdominal surgery are associated with less postoperative stress than conventional surgery. Recent reports concerning laparoscopic cholecystectomy have, however, indicated that the stress response, as measured by intraoperative release of cortisol and catecholamines, is not diminished by the laparoscopic approach and may even be increased in comparison with the open technique.[2–5] The stress response to surgery can be modified by anaesthesia,[6] surgical positioning[7] and probably by the site of the operation.[8]

Three major neurohumoral systems are involved in maintaining arterial pressure and circulating volume: sympathetic nervous system, renin–angiotensin–aldosterone system (RAA) and the vasopressin system.[9 10] These vasopressor systems are counterbalanced by atrial natriuretic peptide (ANP) in the regulation of circulating volume and arterial pressure.[11 12] The major stimulus for ANP secretion from the atrium is atrial stretch caused by increased atrial transmural pressure.[13] An increase in atrial cavity pressure without an increase in atrial transmural pressure (as with cardiac tamponade) does not trigger ANP release.[13] During laparoscopic procedures, creation of pneumoperitoneum increases right and left atrial intraluminal pressures.[14–16] There are conflicting views on whether or not increased central pressures represent increased central blood volume or increased intrathoracic pressure caused by pneumoperitoneum.[14–16]

The neuroendocrine responses to upper and lower abdominal operative laparoscopy have not been compared. Although similar, the two have significant procedural differences. The first aim of this study

Correspondence to E. A. H.

therefore was to determine if neuroendocrine responses associated with upper and lower abdominal laparoscopy have clinically relevant differences. Second, we examined the correlation between changes in cardiac filling pressures and release of ANP.

## Patients and methods

The study was approved by the Ethics Committee of Kuopio University Hospital and Kuopio University, and written informed consent was obtained from each patient. We studied 16 ASA I–II patients undergoing elective laparoscopic cholecystectomy (LC group) and 19 ASA I–II patients undergoing elective laparoscopic hysterectomy (LH group). Patients with significant cardiovascular, hepatic or renal disease, and those using some angiotensin converting enzyme inhibitors were excluded.

All patients were premedicated with diazepam 10–15 mg orally. Patients also received their usual morning medication, if any, except diuretics. After transfer to the operating theatre, i.v. infusion of 0.9% NaCl solution was started at a rate of 5 ml $kg^{-1}$ $h^{-1}$ for 1 h and continued at a rate of 2.5 ml $kg^{-1}$ $h^{-1}$ thereafter. A radial artery cannula and a 7.5-French gauge thermodilution pulmonary artery catheter for haemodynamic measurements and blood sampling were introduced under local anaesthesia. Mean arterial pressure (MAP), mean central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP) and cardiac output (CO) were recorded by a haemodynamic monitor (AS/3, Datex Corp., Finland). The monitor calculated cardiac index (CI=CO/body surface area) and systemic vascular resistance index (SVRI=(MAP−CVP)×80/CI). The pressure transducers were located at the level of the right atrium. Haemodynamic data were collected simultaneously with blood sampling.

### ANAESTHESIA AND SURGERY

The same anaesthetic technique was used in all patients. Anaesthesia was induced with glycopyrronium 0.004 mg $kg^{-1}$, diazepam 2.5–10 mg, thiopentone (mean 3.9 mg $kg^{-1}$), fentanyl 0.1 mg and vecuronium 0.1 mg $kg^{-1}$. After tracheal intubation, general anaesthesia was maintained with up to 1 MAC of isoflurane and 35% oxygen in an oxygen–air mixture. Additional doses of fentanyl 0.05–0.1 mg and vecuronium 1–2 mg were given when needed. An extra i.v. infusion of colloid solution (6% hydroxyethyl-amylopectinase, Plasmafusin, Pharmacia) in 250-ml doses up to 500 ml was given if PCWP was less than 4 mm Hg before laparoscopy. During anaesthesia minute ventilation was adjusted to maintain end-tidal $P\text{CO}_2$ at 4.5–5.0 kPa by controlled mechanical ventilation. Pneumoperitoneum for laparoscopy was produced with a Verres' needle using a carbon dioxide insufflator, and intra-abdominal pressure was maintained automatically at the desired level (13–16 mm Hg, recorded by the insufflator). All operations were performed successfully by the laparoscopic approach. Six hysterectomy patients experienced haemorrhage (more than 200 ml) during operation (range 300–1000 ml). Blood loss was replaced with 6% hydroxyethyl-amylopectinase (Plasmafusin, Pharmacia) and red blood cells. During the first 2 h in the recovery room, fentanyl 0.05 mg i.v. was administrated for pain when needed.

### BLOOD SAMPLING

Baseline arterial blood samples were obtained approximately 30 min after catheterization with the patient resting in bed (baseline). Subsequent awake samples were obtained at 5 min after placing the patient on the operating table to the position used during laparoscopy: 15–20° head-up for cholecystectomy or 25–30° head-down for hysterectomy. Blood samples during surgery were obtained at the end of laparoscopy before desufflation of the intra-abdominal gas and with the patient still in the head-up or head-down position. Postoperative blood samples were obtained 2 h after surgery in the recovery room.

### ASSAYS

Blood for adrenaline and noradrenaline assays was collected in ice-chilled vacuum tubes containing glutathione and ethylene-glutamine-tetra-acetic acid, for renin and NT-proANP assays in ice-chilled tubes containing EDTA, and for cortisol measurements in plain serum tubes. Samples for plasma separation were centrifuged within 10 min and stored at −20 °C (for catecholamine assays at −70 °C) until analysed. Blood samples for cortisol measurement were handled as above after clotting.

Adrenaline and noradrenaline concentrations in plasma were analysed by high performance liquid chromatography with coulometric detection, as described in detail elsewhere.[17] The detection limits of adrenaline and noradrenaline were 0.1 nmol $litre^{-1}$ and 0.075 nmol $litre^{-1}$, respectively. Intra- and inter-assay coefficients of variations (cv) for adrenaline were 11% and 11% at 0.26 nmol $litre^{-1}$ and for noradrenaline, 7.8% and 15.2% at 1.42 nmol $litre^{-1}$, respectively. The normal ranges for adrenaline and noradrenaline are 0.32 (0.19) nmol $litre^{-1}$ and 0.98 (0.27) nmol $litre^{-1}$, respectively. Cortisol concentrations in serum were determined with a commercially available direct radioimmunoassay (Orion Diagnostica Cortisol [$^{125}$I], Orion Co, Turku, Finland). The sensitivity of the method (the smallest detectable concentration) is approximately 4–7 nmol $litre^{-1}$, the intra-assay cv is 2.1–4.1% and the inter-assay cv is 4.3–9.0% within the measurement range; the normal range for morning concentrations is 150–650 nmol $litre^{-1}$. Plasma renin activity was measured with the Medix Angiotensin I Test (Medix Biochemica Corporation, Kauniainen, Finland). The detection limit of the assay was <0.2 μg $litre^{-1}$ $h^{-1}$ (normal range 0.9–2.0 μg $litre^{-1}$ $h^{-1}$). Intra- and inter-assay cv were 15.4% and 7.7% at 1.0 μg $litre^{-1}$ $h^{-1}$, 8.9% and 5.6% at 3.3 μg $litre^{-1}$ $h^{-1}$, and 8.7% and 2.6% at 7.8 μg $litre^{-1}$ $h^{-1}$, respectively.

NT-proANP was assayed directly from plasma as follows. Standards and samples (25 µl) in duplicate were incubated with 200 µl of radioiodinated NT-proANP and 200 µl of rabbit anti-human NT-proANP antiserum (final dilution 1/40 000) overnight at +4 °C. Bound and free fractions were separated by double antibody precipitation in the presence of polyethylene glycol. The sensitivity of the assay was 0.75 fmol/tube, the inter-assay cv was 5.3% at 0.275 nmol litre$^{-1}$ and 9.3% at 0.128 nmol litre$^{-1}$. The antiserum cross reacts fully with proANP$_{1\text{-}126}$ and proANP$_{1\text{-}98}$ but does not recognize ANP (proANP$_{99\text{-}126}$), B-type natriuretic peptide or C-type natriuretic peptide (cross reaction <0.01%).[18] Basal plasma concentration of NT-proANP in healthy adults is 0.355 (0.123) nmol litre$^{-1}$.

### STATISTICAL ANALYSIS

Results are expressed as mean (SEM), except patient data, which are given as mean (SD) and range. Correlations between variables are reported by the Pearson correlation coefficients. All statistical analyses were performed with a statistical software package (SPSS/PC+, SPSS Inc., Chicago, IL, USA). Data were analysed by one- and two-way analysis of variance for repeated measurements. Statistically significant differences were isolated by means of the paired Student's *t* test (within group) and by the unpaired Student's *t* test (between groups). The relationships between NT-proANP and CVP, and between NT-proANP and PCWP were studied by linear regression analysis. The level of significance was $P<0.05$ unless otherwise indicated.

## Results

There were no significant differences in patient characteristics between the laparoscopic cholecystectomy (LC) and laparoscopic hysterectomy (LH) groups (table 1). Laparoscopy was more prolonged in the LH group than in the LC group.

There were no significant differences between the two groups in any of the hormones measured under awake baseline conditions (fig. 1). Noradrenaline concentration increased both in the head-up and head-down positions. The decrease in NT-proANP in the head-up position and the increase in NT-proANP in the head-down position were not significant compared with baseline, but the difference between the LC and LH groups was significant ($P=0.006$).

Laparoscopy with carbon dioxide pneumoperitoneum increased serum cortisol to concentrations more than two times higher than those detected before surgery. Plasma noradrenaline increased in both groups, but concentrations were significantly higher in the LC group than in the LH group

*Table 1* Patient characteristics and duration of laparoscopy, surgery and anaesthesia (mean (SD) [range])

| | Cholecystectomy group | Hysterectomy group | *P* (between groups) |
|---|---|---|---|
| Age (yr) | 45 [19–69] | 44 [32–69] | ns |
| Weight (kg) | 71 9 (11.0) [55–91] | 67.0 (10.3) [49–86] | ns |
| Height (cm) | 163 (5.5) [152–171] | 163 (5.4) [152–173] | ns |
| Body surface area (m$^2$) | 1.77 (0.14) [1 56–1.97] | 1.72 (0.15) [1 45–1.99] | ns |
| Body mass index (kg m$^{-2}$) | 26.9 (3.8) [20–33] | 24.9 (2 8) [19–31] | ns |

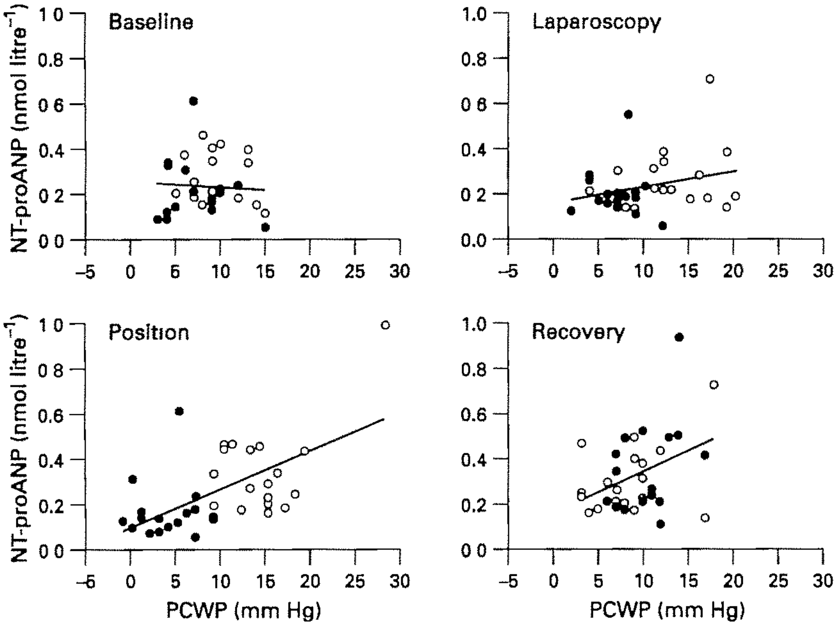

*Figure 2* Correlations and linear relationship between pulmonary capillary wedge pressure (PCWP) and NT-proANP concentrations at baseline, during awake head-up or head-down positioning (position), during laparoscopy and during recovery in the cholecystectomy (●) and hysterectomy (○) patients. Line fit by method of least squares.

($P=0.02$). Plasma adrenaline increased in both groups, but plasma renin activity (PRA) increased only in the LC group during laparoscopy compared with baseline. Plasma NT-proANP concentrations were higher in the LC group and lower in the LH group during laparoscopy compared with awake values in the same surgical position. NT-proANP concentrations during laparoscopy were not significantly different from baseline awake concentrations.

At 2 h after surgery, serum cortisol concentrations increased further from laparoscopic concentrations in the LH group. Plasma adrenaline concentrations were still above baseline in both groups. In the LH group plasma noradrenaline concentrations were increased above baseline, but in the LC group they had returned to near baseline. Plasma NT-proANP concentrations were increased above laparoscopic and baseline concentrations after surgery in the LC group ($P=0.01$).

MAP and SVRI increased, and cardiac index (CI) decreased, both in the head-up and head-down positions in awake patients (table 2). PCWP and CVP decreased in the head-up position and increased in the head-down position. During laparoscopy, CI decreased and SVRI increased compared with baseline in both groups. Pneumoperitoneum increased PCWP and CVP in head-up laparoscopy, but in head-down laparoscopy only CVP increased further compared with the same position in awake patients. During recovery, most of the values approached baseline, although CI, PCWP and CVP remained increased in the LC group.

For all patients grouped together ($n=35$), linear correlations between NT-proANP and PCWP were poor under baseline conditions ($r=0.06$, $P=0.75$)

and during laparoscopy ($r$=0.27, $P$=0.11). However, during awake head-up or head-down positions and during recovery, correlations were significant ($r$=0.60, $P$=0.0002, and $r$=0.40, $P$=0.017, respectively). Similar correlations (with slightly lower $r$ values) were found between NT-proANP and CVP, with correlation coefficients of 0.04, 0.27, 0.48, and 0.32 at baseline, during laparoscopy, during awake head-up or head-down positions and during recovery, respectively. The possible effect of blood loss in the LH group on NT-proANP values during laparoscopy and recovery was examined, and no significant correlations were found ($P$=0.79, $P$=0.44).

Figure 2 shows the linear correlations between NT-proANP and PCWP during the different phases of the study.

## Discussion

We have demonstrated that laparoscopy either in the head-up position during cholecystectomy or in the head-down position during hysterectomy caused marked activation of neuroendocrine responses, reflected by increases in serum cortisol and plasma catecholamine concentrations. We found no significant differences between upper and lower abdominal surgical laparoscopy in serum cortisol or plasma adrenaline concentrations or in plasma renin activity. Plasma noradrenaline concentrations were significantly higher in the cholecystectomy patients which may not be an unexpected result considering the prominent sympathetic sensory innervation of the upper abdomen. Varying the surgical position may also have contributed to the difference. Head-down tilt compared with the supine position during lower abdominal surgery has been reported to be associated with decreased sympathetic nervous system activity and lower plasma noradrenaline concentrations.[7] Further, higher noradrenaline secretion has generally been found in the upright compared with the supine position in awake volunteers.[19]

NT-proANP is secreted from the heart in equimolar quantities with the biologically active ANP. It is, however, a much more stable peptide in the circulation than ANP, which is eliminated rapidly from blood by receptor binding and enzymatic degradation.[18] The close correlation between NT-proANP and ANP has been demonstrated previously in patients with cardiac disease.[20 21] Stretch of cardiac atria is the most potent stimulus for the ANP system, and PCWP and CVP have been shown to correlate positively with release of natriuretic peptides from the atria.[20 22] Our results, however, showed that during pneumoperitoneum there was a poor correlation between the activity of the ANP system, as reflected by plasma NT-proANP concentrations, and measured intraluminal cardiac filling pressures, reflected by PCWP and CVP. The unchanged NT-proANP concentrations, in spite of increased filling pressures during pneumoperitoneum, indicate the surprising conclusion that atrial transmural pressures do not increase during the procedure. Inflation of the abdomen associated with the laparoscopic technique may interfere with venous return, thus counteracting the increase in central blood volume otherwise resulting from the head-down tilt.

Plasma ANP concentrations have been shown to decrease or remain stable after severe blood loss in animals.[23 24] In contrast, moderate blood loss (up to 1000 ml) in healthy volunteers did not induce significant decreases in ANP release.[25] Some patients in our hysterectomy group experienced haemorrhage up to 1000 ml. Blood loss was replaced with colloid solutions and red blood cells, and the continuously monitored patients did not show signs of hypovolaemia at any phase of the study.

Despite the fact that the magnitude of the neuroendocrine response appeared to be correlated directly with the extent of the surgical wound[1] and that minimal access techniques appeared to cause less postoperative stress than conventional surgery, intraoperative increases in circulating cortisol and catecholamine concentrations have been shown to be similar[2–4] or even larger[5] with the laparoscopic compared with the open technique. Cooper and co-workers showed that even short-duration gynaecological laparoscopy produced significant hormonal and glycaemic responses.[26] This is in keeping with our results in which both upper and lower abdominal laparoscopic surgery were associated with clear activation of the HPA axis and the catecholamine system.

# Effects of clonidine on the pituitary hormonal response to pelvic surgery

F. M. LYONS, S. BEW, P. SHEERAN AND G. M. HALL

## Summary

We have investigated the effects of the central $\alpha_2$ adrenoreceptor agonist, clonidine, given i.v. before induction of anaesthesia, on the haemodynamic and endocrine responses to pelvic surgery. Twenty patients were allocated randomly to receive either clonidine 3 $\mu$g kg$^{-1}$ or an equivalent volume of 0.9% sodium chloride solution. Arterial pressure, heart rate, and circulating concentrations of cortisol, growth hormone, glucose and lactate were measured during and in the 24 h after total abdominal hysterectomy. Arterial pressure and heart rate decreased significantly in the clonidine group during surgery and in the early postoperative period. There were no differences between groups in serum cortisol or growth hormone concentrations throughout the study. Despite an effective decrease in the cardiovascular response to surgery, clonidine 3 $\mu$g kg$^{-1}$ i.v. had no significant effect on pituitary hormone secretion. (*Br. J. Anaesth.* 1997; **78**: 134–137)

**Key words**

Hormones, glucocorticoid. Hormones, growth. Surgery, gynaecological. Surgery, hormonal response. Sympathetic nervous system, clonidine. Metabolism, glucose.

The antihypertensive drug clonidine is a centrally acting $\alpha_2$ agonist.[1] It is useful as a premedicant because of its sedative, anxiolytic and analgesic effects. Clonidine decreases the amount of isoflurane and fentanyl needed to supplement general anaesthesia and may offer myocardial protection to patients with cardiovascular disease.[2,3] Recognized neuroendocrine effects of clonidine include inhibition of sympathoadrenal activity with decreased circulating catecholamine concentrations,[4,5] decreased secretion of adrenocorticotrophic hormone (ACTH) and cortisol,[6] and decreased secretion of insulin and enhanced growth hormone release (GH).[7,8] After i.v. administration of clonidine, the maximum effect occurs within 60–90 min and the terminal elimination half-life is in the range 20–25 h.[9,10]

Two studies have examined the effects of oral premedication with clonidine on the early haemodynamic and endocrine changes associated with surgery. One study investigated neurosurgical patients and showed a decrease in the cortisol response with clonidine.[11] The other showed that clonidine added to diazepam premedication, compared with diazepam alone, did not alter the cortisol and GH response to surgery.[12] The purpose of this study was to examine the effects of preoperative i.v. clonidine on the haemodynamic and endocrine responses, during and in the 24 h after pelvic surgery.

## Patients and methods

Approval for the study was obtained from the local Ethics Committee for clinical research (reference No. 94.05.17). Written informed consent was obtained from each patient .

We studied 20 patients with benign disease undergoing total abdominal hysterectomy. Patients had no history of endocrine or cardiovascular disease. They were allocated randomly using sealed envelopes to receive either clonidine ($n=10$) or 0.9% sodium chloride (NaCl) solution ($n=10$) i.v. before induction of anaesthesia. Previous work indicated that a sample size of 20 patients had a power of 90% to detect a standardized difference of 1.5 in heart rate and systolic arterial pressure, at a significance level of 5%.

Patients did not receive premedication. On arrival in the anaesthetic room an i.v. cannula was inserted for drug administration. Non-invasive monitoring of heart rate, arterial pressure and arterial oxygen saturation was commenced. A central venous catheter was inserted, via the antecubital fossa, for fluid administration and blood sampling. Baseline measurements of heart rate, arterial pressure and arterial oxygen saturation were recorded, and a blood sample was obtained for measurement of circulating hormones and metabolites. Patients then received either clonidine 3 $\mu$g kg$^{-1}$ in 0.9% NaCl solution 20 ml or 0.9% NaCl solution 20 ml , i.v. over 15 min.

General anaesthesia was induced in all patients with fentanyl 4 $\mu$g kg$^{-1}$ and a sleep dose of thiopentone. Vecuronium 0.1 mg kg$^{-1}$ was used to facilitate

tracheal intubation. Anaesthesia was maintained with 0.5–1.5% isoflurane and 60% nitrous oxide in oxygen. Mean end-tidal isoflurane concentrations were 0.6 (SEM 0.1) % in the clonidine group and 0.7 (0.1) % in the saline group. All patients received 0.9% NaCl 6 ml kg$^{-1}$ h$^{-1}$ in the intraoperative period and 2 ml kg$^{-1}$ h$^{-1}$ after operation as i.v. maintenance fluid. Blood losses were replaced with an equivalent volume of Gelofusin. After operation, patients received patient-controlled analgesia with morphine.

Blood samples were obtained and cardiovascular measurements made at the following times: before administration of placebo or clonidine, at skin incision (0 h) and at 1, 2, 4, 6, 12 and 24 h after skin incision. All samples were analysed in duplicate for blood glucose and lactate concentrations by methods described previously.[13] Serum concentrations of cortisol and GH were measured with commercially available enzyme linked immunoassay kits. The sensitivity of the assay was 7.3 nmol litre$^{-1}$ for cortisol (Milenia Cortisol EIA) and 0.11 miu litre$^{-1}$ for growth hormone (Medgenix-HGH-EASIA). Intra-assay coefficients of variation were 3.2% for cortisol and 2.1% for GH; inter-assay coefficients of variation were 8% for cortisol and 7% for GH. Packed cell volume (PCV) was measured using a microcapillary method. The investigator undertaking the analysis was unaware of the identity of the sample.

Statistical analysis was undertaken using Statview SE+ Graphics computer software (Abacus concepts, Berkeley, CA, USA). GH values were not distributed normally and are shown as median (range); values below the sensitivity of the GH assay were ascribed that value. All other hormonal, metabolic and cardiovascular variables are presented as mean (SEM). Differences within groups with respect to baseline samples were assessed by two-way analysis of variance with Dunnet's test, and between-group differences by one-way analysis of variance. GH data were analysed using Friedman's two-way analysis of variance and the Kruskal–Wallis test for differences between groups. $P<0.05$ was accepted as significant.

## Results

The groups were similar in mean age (control 44 (range 36–52) yr, clonidine 46 (37–64) yr), body weight (control 66 (55–82) kg, clonidine 67 (60–86) kg), duration of surgery (control 80 (50–110) min, clonidine 75 (40–110) min) and 24-h morphine consumption (control 46 (19–87) mg, clonidine 54 (33–76) mg). Two patients received atropine 0.3 mg i.v. for bradycardia (heart rate ≤45 beat min$^{-1}$).

### CARDIOVASCULAR CHANGES

Heart rate was unchanged throughout the study in the control group from the baseline value of 80 beat min$^{-1}$. In the clonidine group, heart rate decreased significantly from the baseline value of 78 beat min$^{-1}$ until 4 h after operation ($P<0.05$). There was a significant difference in heart rate between the groups at skin incision ($P<0.01$), and at 1 and 2 h ($P<0.05$).

Systolic arterial pressure decreased significantly from baseline at skin incision and at 4 h ($P<0.05$) in the control group. In the clonidine group, systolic pressure decreased significantly from baseline at skin incision and at 1, 2, 4, 6 ($P<0.01$) and 12 h ($P<0.05$). There was a significant difference in systolic arterial pressure between the groups at skin incision ($P<0.01$), and at 1 and 2 h ($P<0.05$).

Diastolic arterial pressure did not change from baseline in the control group throughout the study. In the clonidine group, diastolic pressure decreased significantly from baseline at skin incision, 1 h ($P<0.01$) and 4 h ($P<0.05$). There was a significant difference between groups at skin incision ($P<0.01$) and at 2 h ($P<0.05$).

### CIRCULATING HORMONES AND METABOLITES (TABLE 1)

Serum concentrations of cortisol increased significantly from a baseline value of 603 nmol litre$^{-1}$ at 1, 2, 4 and 6 h ($P<0.05$) in the control group, and

*Table 1* Mean (SEM) blood glucose, blood lactate, and serum cortisol concentrations and packed cell volume (PCV) Growth hormone concentrations are presented as median (range). Within group differences· *$P<0$ 05; ** $P<0.01$. B=Baseline

from a baseline value of 536 nmol litre$^{-1}$ at 1, 2, 4 ($P<0.01$) and 6 h ($P<0.05$) in the clonidine group. However, there were no significant differences between groups.

In both groups serum concentrations of GH increased transiently from baseline values at skin incision and at 1 h ($P<0.05$ in the control group, $P<0.05$ and $<0.01$ in the clonidine group). There were no significant differences between groups.

Blood glucose values increased significantly at 2 ($P<0.01$), 4, 6 and 12 h ($P<0.05$) in the control group and at all times, other than skin incision, in the clonidine group ($P<0.05$). At 1 h, blood glucose concentration was significantly greater in the clonidine group than in the control group ($P<0.05$).

Blood lactate concentrations did not change significantly throughout the study in the control group. In the clonidine group, blood lactate concentration was significantly lower than baseline at 4 h ($P<0.05$), and was also significantly lower at this time compared with the control group.

PCV decreased from baseline in both groups of patients, but this change was not statistically significant. There was no significant difference between groups.

## Discussion

We have shown that clonidine 3 $\mu$g kg$^{-1}$ i.v. decreased the cardiovascular, but not the pituitary hormonal, response to pelvic surgery.

The physiological response to surgical trauma includes an increase in circulating concentrations of the catabolic hormones, such as catecholamines, cortisol and GH, and a concomitant decrease in plasma concentrations of the anabolic hormones, such as insulin and testosterone.[14] Most anaesthetic techniques do not prevent these changes, but high doses of opioids and regional anaesthesia can modify the pituitary and sympathoadrenal response to surgery.

In this study, patients treated with clonidine had a decreased haemodynamic response to surgery, as shown by the lower values of heart rate, and systolic and diastolic arterial pressures, for 4 h after surgical incision. Thus the dose and method of administration of clonidine were adequate to test the hypothesis that clonidine could attenuate pituitary hormone secretion in addition to the cardiovascular response. However, we have clearly demonstrated no difference in GH and cortisol values after administration of clonidine.

Two previous studies have reported variable effects of clonidine on serum cortisol changes associated with surgery. In a study of 20 neurosurgical patients in which a significant decrease in serum cortisol concentration was reported, no samples were collected before oral administration of clonidine, and patients receiving high doses of steroids for less than 3 days were not excluded.[11] Pouttu and colleagues studied 21 patients undergoing breast surgery and found no difference in serum cortisol and GH concentrations when clonidine premedication was used. However, interpretation of the data is complicated by the use of diazepam premedication in the clonidine and control groups,[12] as benzodiazepines are known to alter ACTH and GH secretion.[15,16] In both of these studies, blood sampling was continued for a maximum of 3 h after surgery. As clonidine has a long half-life, neither study has assessed the effect of clonidine over an appropriate time period.

The hyperglycaemic response to surgery is multifactorial and results from increased secretion of catabolic hormones, particularly adrenaline and cortisol. Blood glucose concentrations increased significantly in both groups after surgery. Clonidine did not attenuate the hyperglycaemic response, despite the sympathoadrenal inhibition indicated by the haemodynamic changes. Paradoxically, blood glucose was significantly greater in the clonidine group 1 h after skin incision. A transient glycaemic effect of clonidine with an acute dose has been demonstrated, and clonidine is associated with direct inhibition of insulin secretion.[7,9] Our findings suggest that any hypoglycaemic effect of clonidine secondary to decreased sympathoadrenal activity is overcome by a direct inhibitory effect on the β-cells of the pancreas, and other catabolic hormones released in response to surgical stress.

We conclude that clonidine 3 $\mu$g kg$^{-1}$ i.v. at induction of anaesthesia failed to alter the pituitary–adrenal response to pelvic surgery.

# Modelling the volume of expandable body fluid spaces during i.v. fluid therapy

L. STÅHLE, A. NILSSON AND R. G. HAHN

## Summary

We have developed mathematical models to represent the changes in volume of fluid spaces associated with i.v. administration of a crystalloid solution. Input data for parameter estimations were dilution of blood, measured as reduction of blood haemoglobin concentration. The models were based on the assumption that the body strives to maintain volume homeostasis of fluid spaces and that the rate of restoration is a function of deviation from resting volume. Two models were derived; the first had a single fluid space into which fluid was administered and from which fluid left, the other model had a second fluid space communicating with the first. These models may be useful in the description and analysis of the effects of i.v. fluid therapy. (*Br. J. Anaesth.* 1997; **78**: 138–143)

**Key words**
Fluids, i.v. Fluid balance. Pharmacokinetics. Model, mathematical.

The distribution of water between fluid compartments, such as the intracellular and extracellular spaces, has been studied in classical physiological work.[1] Tritiated water injected in trace amounts has also been used to describe the disposition of water in an organism.[2] In these studies, the water molecules have been assumed to be distributed within a fluid space of constant volume. Another, and quite different, aspect of water distribution is the changes in volume of fluid spaces when large, as opposed to trace, amounts of water are added to or removed from the body. In this situation, the infused water changes the volume of the fluid compartment it occupies. To our knowledge, this aspect of fluid therapy has not been studied previously. Therefore, we have developed mathematical models of changes in the volumes of the body fluid spaces applicable during and after volume loading.

## Methods

### THE MODELS

The models described here are referred to as volume-of-fluid-space (VOFS) models (fig. 1). To give the reader an image of the models, they may be thought of as water-filled balloons, because some features can be comprehended more easily by thinking of a fluid space as a volume surrounded by an elastic wall.

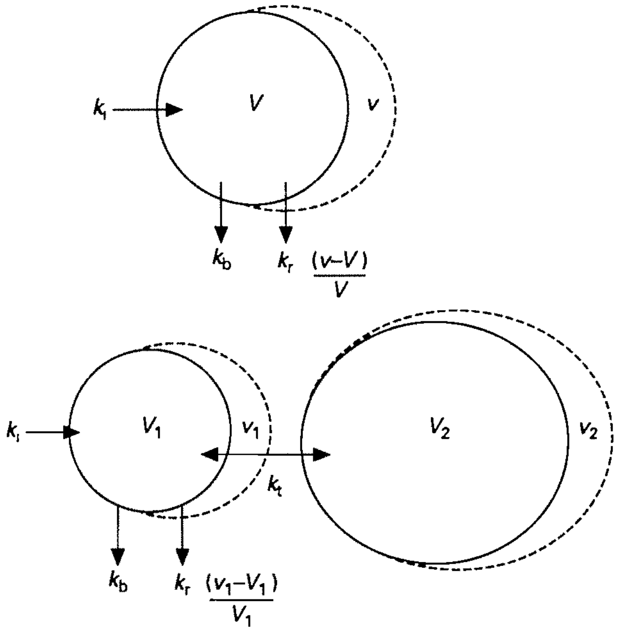

*Figure 1* Diagrammatic representations of the single-fluid space model, VOFS1 (upper) and the two-volume fluid space model, VOFS2 (lower). The broken lines indicate expansion of the fluid spaces.

The single-fluid space model, VOFS1, is based on the following assumptions: (1) during infusion, fluid enters an expandable fluid space of volume $v$, at a constant rate, $k_i$; (2) the expandable fluid space has a target volume $V$, which the body strives to maintain; (3) volume $v$ changes by fluid being eliminated from the fluid space at a basal rate, $k_b$ (perspiration and basal diuresis), and at a controlled rate. The controlled rate is proportional by a constant $k_r$ to the relative deviation of $v$ from the target volume $V$.

From these assumptions, the following differential equation can be derived:

HAHN, MD, PHD, Department of Anaesthesia, Soder Hospital, S-118 83 Stockholm, Sweden. Accepted for publication: October 1, 1996.

Correspondence to R. H.

$$dv/dt = k_i - k_b - k_r\,(v - V)/V \qquad (1)$$

The solution to this equation is given in the appendix.

The two-fluid space model, VOFS2, is based on the following assumptions: (1) during infusion, fluid enters a primary expandable fluid space of volume $v_1$ at a constant rate, $k_i$; (2) there is a secondary expandable fluid space of volume, $v_2$, exchanging fluid with the primary fluid space; (3) $v_1$ changes through exchange with the secondary fluid space and as a result of fluid being eliminated from the primary fluid space at a basal rate, $k_b$, and at a controlled rate; (4) the primary and secondary fluid spaces have target volumes $V_1$ and $V_2$ which the system strives to maintain by acting upon the controlled elimination mechanism in proportion, $k_r$, to the relative deviation from the target volume of the primary fluid space and by acting upon the fluid exchange mechanism; (5) the net rate of fluid exchange between the fluid spaces is proportional to the difference in relative deviations from the target volumes by a constant $k_t$.

From these assumptions the following system of differential equations can be derived:

$$dv_1/dt = k_i - k_b - k_r\,(v_1 - V_1)/V_1 - k_t\,((v_1 - V_1)/V_1 - (v_2 - V_2)/V_2) \qquad (2)$$

$$dv_2/dt = k_t\,((v_1 - V_1)/V_1 - (v_2 - V_2)/V_2) \qquad (3)$$

The analytical solutions to these differential equations are presented in the appendix.

## NUMERICAL METHODS FOR ESTIMATING PARAMETERS

The rate constants $k_i$ and $k_b$ in equations (1–3) can be considered known; the first because it is under experimental control and the second because it (basal fluid loss) is a well established, but admittedly variable, physiological phenomenon. Also, the ratio $(v_1 - V_1)/V_1$ is known because it is the measured dilution of blood. This holds irrespective of whether $v_1$ corresponds only to blood volume or to blood volume and any fluid space which is in near instantaneous equilibrium with blood. The remaining variables $k_t$, $k_r$, $V_1$ and $V_2$ have to be estimated from the experimental data. This can be done by least-squares fitting of the solutions of equations (1–3) (see appendix) to experimental data.

We chose the random search method for the least-squares fitting procedure to obtain the best estimates of the unknown variables in the general form of the dilution–time curves in VOFS1 and VOFS2.[3] The variation in the parameters to be estimated was initially 0.1×rnd×pv, where rnd is a uniform random number between −1.0 and +1.0 and pv is the presently "best" value of the parameter. The process went on until no improvement of the fit was obtained in 15 trials and then the factor 0.1 was multiplied by 0.3×pv and the process repeated until no improvement was found within 0.001×pv. Calculations were performed on a Macintosh computer using Matlab version 3 (Math Works Inc., Notich, MA, USA). Experience from a large number of experiments analysed showed that convergence was rapid for data with a better fit to VOFS2 while poorly fitting data were accompanied by slow convergence.

## EXPERIMENTAL DATA

The curve-fitting procedure was illustrated by data obtained from two volunteer experiments where Ringer's acetate solution 25 ml $kg^{-1}$ was given by constant rate i.v. infusion over 30 min. The experiments were approved by the Ethics Committee at South Hospital, Stockholm.

Dilution occurring during i.v. infusion of crystalloid solutions can be assumed to indicate an increase in the volume of one or more expandable fluid spaces. Although many markers may be used to indicate dilution, we used blood haemoglobin (B-Hb) concentration, as measured by a Technicon H2 (Bayer, Tarrytown, NY, USA) using colorimetry at 546 nm. Plasma volume was taken to be (1−packed cell volume)×blood volume. Because our sampling perturbs the volume of the fluid space

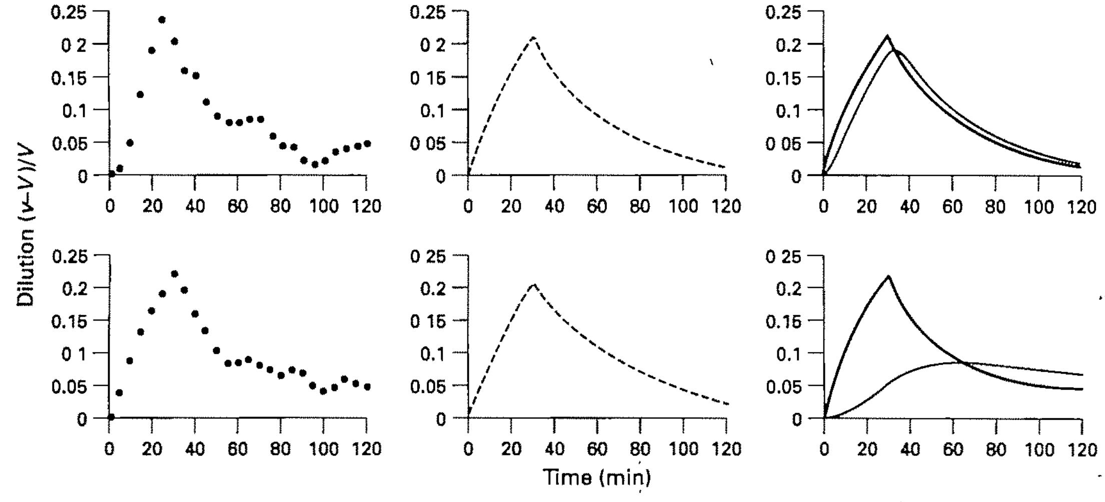

*Figure 2* Plasma dilution–time profiles in two volunteers in whom Ringer's solution 25 ml $kg^{-1}$ was given by i.v. infusion over 30 min (left) Curve-fitting of the same data was performed according to VOFS1 (middle) and VOFS2 (right), the latter showing the modelled dilution of both the primary (thick line) and secondary (thin line) fluid space. A statistical test applied on the residual errors showed that VOFS1 was most suitable for presentation in first volunteer (top row) while VOFS2 was more appropriate in the second volunteer (bottom row).

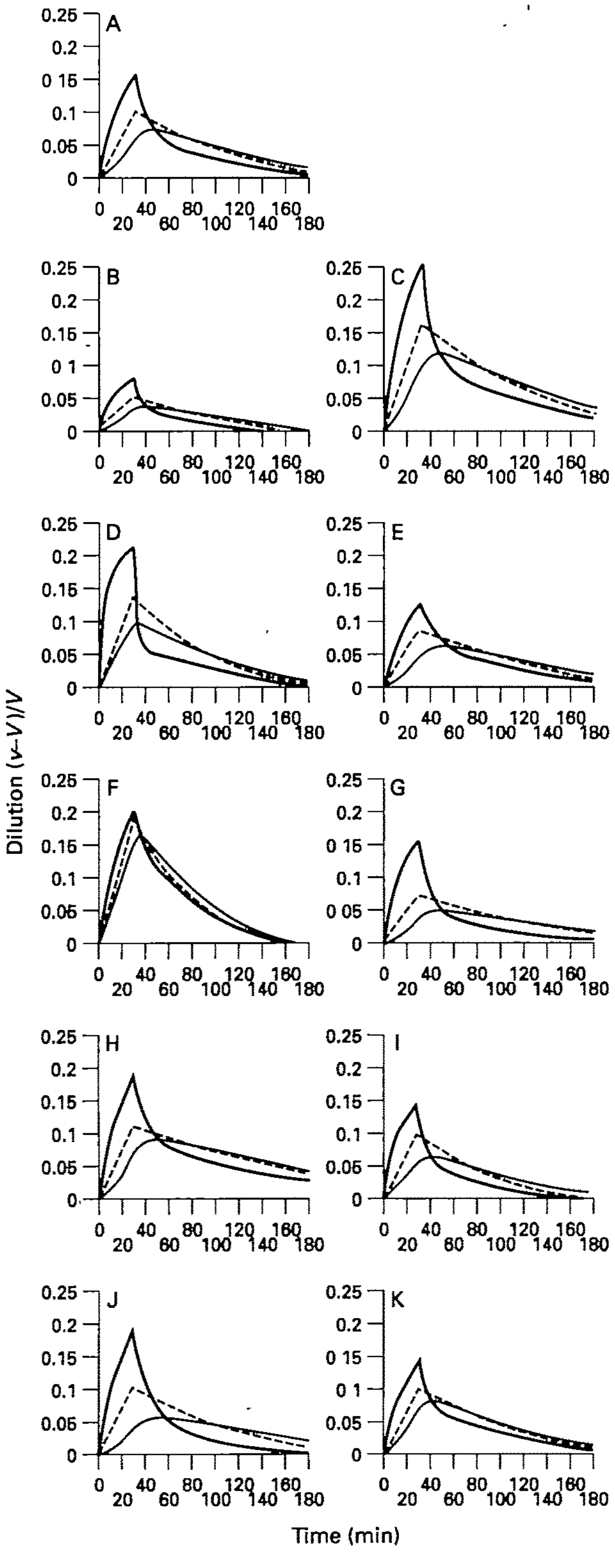

*Figure 3* Simulation of the dilution–time profiles of the primary (thick line) and secondary (thin line) fluid spaces in the VOFS2 with parameters set as shown in table 2. The corresponding curve (broken line) for the VOFS1 model is also shown.

measured, a correction was introduced based on multiplying the sample volume by the sample B-Hb concentration and then subtracting the amount obtained from total body Hb content, as calculated from estimated blood volume.[4] There are several equations available for estimation of total blood volume from the length and height of human subjects; all give similar results. In this study, the equation of Nadler, Hidalgo and Bloch[5] was used. The dilution–time curves were analysed according to both the VOFS1 and VOFS2 models and a statistical test was applied to the residual errors to select the best for presentation.[3]

### MODEL SENSITIVITY TO NOISE

Identifiableness of parameters was investigated by simulating "exact" data and then estimating them by least squares. Feeding exact data to the program resulted in an output within the precision preset for the algorithm (less than 0.001).

Simulation of statistical error was also performed. For each parameter combination shown in table 2, $(v_1 - V_1)/V_1$ was calculated for various times. A random, normally distributed error was then added to each value to investigate the sensitivity of the parameter estimations to noise. The size of the error, and the use of an additive error model, were based on the real situation. B-Hb is a method with an SD of approximately 1 unit of measurement, which is less than 1%. When used to estimate dilution of plasma, the difference between two Hb values is used and the relative size of the error becomes larger than the assay precision. However, the relative size of the error also depends on the magnitude of the dilution. We therefore chose to allow the error to be independent of the parameters and dilution in order to mimic the real situation. Thus, the "standard" SD was chosen as 0.010 dilution units corresponding to approximately 1.4 g litre$^{-1}$ Hb units. Inspection of the simulation curves shows that they are slightly worse, in terms of error, than real data. The number of times were 12 (0, 2, 6, 12, 20, 22, 26, 32, 40, 50, 90 and 120 min after the start of infusion). For every parameter combination, 25 data sets were simulated, each with random errors, and fitted. Mean, SD, median and, in some cases, geometric mean were calculated.

## Results

The VOFS1 model was most suitable for presentation in the first volunteer experiment (fig. 2, upper row). In this case, dilution was similar in the primary

*Table 1* Results of volume kinetic analysis of the infusion experiments shown in figure 2. Two adult male volunteers were given Ringer's solution i.v. *VOFS2 is most appropriate when the test value <3.47.

and secondary fluid spaces, which is expected when the VOFS2 model is not significantly "better" than the VOFS1 model. This indicates that the infused fluid diluted a single fluid space. In contrast, VOFS2 was more appropriate in the second volunteer experiment. Here the dilution was different in the primary and secondary fluid spaces (fig. 2, lower row). Data generated in the volume kinetic analyses are shown in table 1.

The reproducibility of the parameter estimates using different seeds for the random number generator was within 1%.

In the simulation of statistical error, the parameters were varied, as shown in table 2 and illustrated

*Table 3* Statistical simulation of the influence of parameter values, experimental conditions and statistical error on the precision and bias of the parameter estimates. $k_b$ was set to 2.5 ml min$^{-1}$. The infusion time was 30 min and 25 simulations were used to obtain the statistics for each parameter combination. SD=standard deviation around the simulated dilution curve, expressed in dilution units

further in figure 3. The results revealed acceptable precision and lack of bias for $V_1$ and $k_r$ (table 3). In contrast, $V_2$ and $k_t$ were more sensitive to statistical error and their distributions were also skewed. There was a negative correlation between estimates of $V_1$ and $k_t$, which illustrates that VOFS is a non-linear model.

## Discussion

The clinical basis for this study was the need for methods that allow estimation of the volumes and kinetics of fluid spaces in the body influenced by i.v. infusion of large amounts of fluids. Such methods may be useful for designing and optimizing i.v. fluid therapy. In fact, little is known of how fluid should be administered to yield a certain volume response. Clinical practice is currently the basis for most schemes used.

There are several fundamental differences between the VOFS and traditional pharmacokinetic models. The latter describe the distribution of a solute into fluid spaces and binding sites, which themselves are assumed not to be affected by the solute. The volume of distribution is considered to be a constant. Similarly, the target volume of a VOFS model is assumed to be constant, but the size of the fluid space expanded is changed. The size of a target volume can be found only by expanding the fluid space because it is the expandability that distinguishes this fluid space from other parts of the body water.

One important feature of our models is that they take into account differences in compliance with regard to volume expansion between tissues. For example, oedema is usually apparent in the lungs and in the subcutaneous tissue of the legs and around the eyes, while the brain and skeleton are almost unaffected. This illustrates that expandable fluid spaces in a patient are not synonymous with the body fluid compartments usually related to in physiological textbooks. Although the water molecules in a crystalloid solution are distributed throughout the extracellular fluid space, the same fluid might expand a much smaller volume.

A concept of two functionally distinct, but communicating, fluid spaces, one which is rigid and the other expandable, is shown in figure 4. The difference between the distribution of a trace amount of water injected, the molecules of which may reach any part of the two connected fluid spaces, and the change in volume resulting from an infusion is crucial for the understanding of the VOFS models. A component necessary for estimation of the size of the expandable volume is the existence of the measurable substance confined exclusively to the sampled space. Blood haemoglobin fulfils this criterion.

To avoid confusion, the terminology for the VOFS models was chosen to differ from that used in classical pharmacokinetics. For example, the volume of distribution and clearance of the infused water molecules vary during i.v. infusion. The target volume is a more suitable term as it remains constant. Apart from the differences in terms of interpretation, the mathematical solutions and data analysis have much in common with those used for compartmental models in traditional pharmacokinetics. The VOFS models are based on the assumption that plasma dilution follows a curve with a monoexponential or biexponential component. Non-linear least-squares regression fitting is performed on patient data to obtain estimates of the unknown parameters in these equations. Thereafter, the analytical solutions to the differential equations based on the VOFS model assumptions are used to calculate the sizes of the expandable fluid spaces and the kinetic constants determining the distribution of fluid.

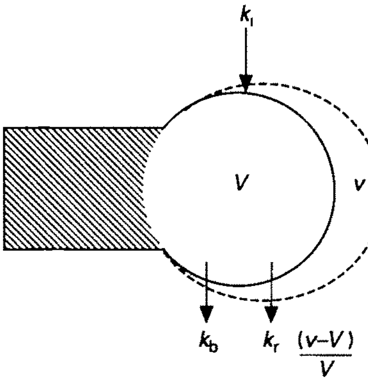

*Figure 4* Illustration of the difference in principle between trace amount pharmacokinetics and volume kinetics. A water molecule entering the fluid space consisting of one expandable portion and one rigid portion can be found anywhere and therefore has a volume of distribution, being the sum of the two portions of the entire fluid space. In terms of volume, however, only the expandable portion of the fluid space is influenced by added water molecules.

The results of the simulations of different parameter values demonstrate that dilution of blood varies considerably depending on the sizes of the fluid spaces and the rapidity of the transport between them. It is of interest that our calculations gave the dilution–time profile of a secondary fluid space, which probably corresponds to the extracellular fluid of some peripheral tissues. This has previously been difficult to study. The fact that a secondary fluid space may be detected has implications for the design of optimal i.v. fluid therapy and, possibly, to the choice of strategy in oedema treatment.

The statistical simulations showed some important properties of our model. The non-linearity of the parameters was reflected in a correlation between parameter estimates. This non-linearity also expressed itself in the distributions of $V_2$ and $k_t$, which tended to be positively skewed in some circumstances which can, to some extent, be controlled for in clinical and experimental work. In particular, the dilution measurement needs to be precise because, if the dilution is small owing to a small $k_i$, the error may be very large in comparison with the dilution and result in overestimation of $V_2$ and $k_t$. One method of improving the estimate of the parameters is to use the geometric mean, unless the experimental conditions can be improved by increasing the dose of the fluid given, shortening the infusion time or using a more precise haemoglobin assay.

Approximately 100 i.v. infusions have been carried out for which volume kinetics have been calculated. Our experience with these models is that they "behave well" when real data are applied. Biological findings obtained using the VOFS models, and recommendations for infusion rates, are discussed in subsequent studies.

## Appendix

### SOLUTION OF VOFS1

Equation (1) is readily solved by standard methods[6] giving:

$$\frac{v-V}{V}=\frac{k_i-k_b}{k_r}+\frac{Qe^{-k_r t/V}}{V} \tag{4}$$

Here $Q$=unknown constant which must be determined by initial conditions. At the start of the infusion when $t=0$ it is assumed that $v=V$, giving the solution:

$$\frac{v-V}{V}=\frac{(k_i-k_b)\ (1-e^{-k_r t/V})}{k_r} \tag{5}$$

After infusion, the solution becomes:

$$\frac{v-V}{V}=(W_T+\frac{k_b}{k_r})e^{-k_r(t-T)/V}-\frac{k_b}{k_r} \tag{6}$$

where $w_T=(v(T)-V)/V$, that is the relative volume deviation attained after $T$ minutes of infusion.

### SOLUTION OF VOFS2

The system (equations (2, 3)) has the form of a non-homogeneous system of linear first-order differential equations. A particular solution, the steady state solution $v_{1_p}$=A, $v_{2_p}$=B, is found by setting $dv_1/dt=dv_2/dt=0$, the solution of which is:

$$v_{1_p}=A=\frac{(k_i-k_b+k_r)V_1}{k_r} \tag{7}$$

$$v_{2_p}=B=\frac{(k_i-k_b+k_r)V_2}{k_r} \tag{8}$$

This particular solution is (below) added to the solution of the corresponding homogeneous system of equations to obtain the general solution $v_1$, $v_2$ to the system (equations (2, 3)). After some preliminary calculations, one obtains:

$$v_1=Ee^{Xt}+Fe^{Yt}+A \tag{9}$$

$$v_2=Ge^{Xt}+He^{Yt}+B \tag{10}$$

where

$$X=1/2[-(\frac{(k_r+k_t)}{V_1}+\frac{k_t}{V_2})+\sqrt{(\frac{(k_r+k_t)}{V_1}-\frac{k_t}{V_2})^2+\frac{4k_t^2}{V_1V_2}}] \tag{11}$$

$$Y=1/2[-(\frac{(k_r+k_t)}{V_1}+\frac{k_t}{V_2})-\sqrt{(\frac{(k_r+k_t)}{V_1}-\frac{k_t}{V_2})^2+\frac{4k_t^2}{V_1V_2}}] \tag{12}$$

Note that both $X$ and $Y$ are negative numbers. In order to find G and H, the determinantal equations associated with $X$ and $Y$ can be used to obtain:

$$G=\frac{Ek_t}{V_1X+k_tV_1/V_2} \tag{13}$$

$$H=\frac{Fk_t}{V_1Y+k_tV_1/V_2} \tag{14}$$

The general solution to the system (equations (2, 3)) is therefore:

$$v_1=Ee^{Xt}+Fe^{Yt}+\frac{(k_i-k_b+k_r)V_1}{k_r} \tag{15}$$

$$v_2=\frac{k_tEe^{Xt}}{V_1X+k_tV_1/V_2}+\frac{k_tFe^{Yt}}{V_1Y+k_tV_1/V_2}+\frac{(k_i-k_b+k_r)V_2}{k_r} \tag{16}$$

with $X$ and $Y$ as in equation (11) and equation (12), and E and F are determined by the initial conditions. As in the case of VOFS1 there are two different initial conditions. At the start of the experiment, steady state is assumed and thus $v_1=V_1$ and $v_2=V_2$ at time $t=0$. Thence:

$$V_1=E+F+A \tag{17}$$

$$V_2=\frac{Ek_t}{V_1X+k_tV_1/V_2}+\frac{Fk_t}{V_1Y+k_tV_1/V_2}+B \tag{18}$$

Rewriting to conform with the experimental data, $X$, $Y$, $Q_1$, $Q_2$ and $Q_3$ can be estimated from the dilution data from the following expression, which is valid *during infusion*:

$$w_1=\frac{v_1-V_1}{V_1}=\frac{Ee^{Xt}+Fe^{Yt}+A-V_1}{V_1}=Q_1e^{Xt}+Q_2e^{Yt}+Q_3 \tag{19}$$

where, after some calculations, $Q_1$, $Q_2$, and $Q_3$ are obtained from:

$$Q_1=-Q_2-Q_3 \tag{20}$$

$$Q_2=(k_i-k_b)\frac{1-Z}{k_r(Z-U)} \tag{21}$$

$$Q_3=\frac{(k_i-k_b)}{k_r} \tag{22}$$

where

$$Z=\frac{k_t}{V_2X+k_t} \tag{23}$$

$$U=\frac{k_t}{V_2Y+k_t} \tag{24}$$

The conditions for the solution *after infusion* are $w_{1T}=(v_1(T)-V_1)/V_1$ at $T$ minutes of infusion and correspondingly $w_{2T}=(v_2(T)-V_2)/V_2$. The exponents $X$ and $Y$ are not changed. Prime notation is used to distinguish the parameters valid after infusion from parameters during infusion. For simplification, the time variable $t$ is reset to zero and the solution can be written:

$$\frac{v_1-V_1}{V_1}=Q1'e^{Xt}+Q2'e^{Yt}+Q3' \tag{25}$$

where

$$Q1'=w_{1T}-\frac{Z(w_{1T}+k_b/k_r)-k_b/k_r-w_{2T}}{Z-U}+\frac{k_b}{k_r} \tag{26}$$

$$Q2'=\frac{Z(w_{1T}+k_b/k_r)-k_b/k_r-w_{2T}}{Z-U} \tag{27}$$

$$Q3'=-k_b/k_r \tag{28}$$

# Volume kinetics of Ringer's solution in female volunteers

R. G. HAHN, D. DROBIN AND L. STÅHLE

**Summary**

The kinetics of crystalloid solutions in humans have not been adequately described previously. Therefore, we measured blood haemoglobin concentration during and for 120 min after i.v. infusion of 25 ml $kg^{-1}$ of Ringer's acetate solution over 15, 30, 45 and 80 min, and 12.5 ml $kg^{-1}$ over 30 min in six adult female volunteers. The dilution–time profiles were analysed according to a new kinetic model adapted for fluid spaces. Volume expansion produced by Ringer's solution approached steady state in an exponentially decaying manner when plasma volume had increased by approximately 550 ml. The size of the fluid space expanded by Ringer's solution was only 4.8 litre (95% confidence interval 3.8–5.8 litre) except for the fastest infusion, where it averaged 9.0 litre. The rate of fluid elimination could be predicted as the product of plasma dilution and a constant averaging 95 (95% confidence interval 68–122) ml $min^{-1}$. (*Br. J. Anaesth.* 1997; **78**: 144–148)

**Key words**

Blood, volume. Fluids, i.v. Pharmacokinetics. Model, mathematical.

Expansion of the intravascular volume is an important property of crystalloid solutions given by i.v. infusion. The currently available methods used to describe this effect consist primarily of repeated measurement of blood volume by a radioactive isotope or dye.[1 2] For accurate results, these methods require an unchanged blood volume for 30–40 min during equilibration of the tracer, which makes them poorly suited for studies of non-steady-state conditions during fluid loading, hypotension and surgery. Changes in blood volume may also be indicated by haemodilution[3 4] but this approach has not been adopted widely.

The aim of this study was to describe the disposition of Ringer's solution in the body when infused at different rates using a new kinetic model.[5] We used dilution–time curves to estimate the size of the expandable space(s) into which the fluid is distributed. Pharmacokinetic principles adapted for fluid volumes were used to model the dynamic conditions during volume loading.

## Subjects and methods

Ringer's acetate solution was given on a total of 30 occasions to six healthy female volunteers, aged 23–46 yr (mean 32 yr) and with a body weight of 50–75 kg (mean 60 kg). The study was approved by the local Ethics Committee and each volunteer gave informed consent.

Volunteers ate a light meal (consisting of one cup of coffee, tea or water and one sandwich) at home before going to hospital where the experiments were started at 08:00–10:00. No oral fluid or food was allowed between the morning meal and the end of the study. Volunteers voided, were immediately placed comfortably on a bed, and 20 min of equilibration was allowed before the infusions were started.

Cannulae were placed into the antecubital veins of both arms and Ringer's acetate solution (Pharmacia, Uppsala, Sweden; electrolyte content (mmol $litre^{-1}$): Na 130, K 4, Ca 2, Mg 1, acetate 30 and Cl 110) was infused into one of these veins at a constant rate with the aid of one or several infusion pumps (IVAC 560, San Diego, CA, USA). Volunteers received, in random order and at intervals of at least 1 day, an i.v. infusion of Ringer's acetate 25 ml $kg^{-1}$ over 15, 30, 45 and 80 min, and 12.5 ml $kg^{-1}$ over 30 min.

### MEASUREMENTS

Samples (3 ml) for measurement of blood haemoglobin (B-Hb) concentration using a Coulter Counter STKS (Counter Electronics, Hialeah, FL, USA) were obtained from the venous cannula not used for infusion before the infusion, every 10 min during infusion, and at 0, 5, 10, 15, 20, 25, 30, 60, 80, 100 and 120 min after infusion. After a blood sample was obtained, Ringer's solution 2 ml was injected to flush the cannula and a small discard sample was obtained before each blood sample to avoid undue haemodilution caused by this fluid. The first B-Hb sample in the series was obtained in duplicate and the mean was used in calculations.

In 25 experiments, urine volume was measured after blood had been collected at 30 and 120 min after the infusion had ended.

### CALCULATIONS

Blood volume (BV) before treatment ($BV_0$) was calculated according to Nadler, Hidalgo and Bloch.[6]

---

ROBERT G. HAHN, MD, PHD, DAN DROBIN, MD, Department of Anaesthesia, Soder Hospital, S-118 83 Stockholm, Sweden. LARS STÅHLE, MD, PHD, Department of Clinical Pharmacology, Karolinska Institute, Huddinge University Hospital, S-141 86 Huddinge, Sweden Accepted for publication: October 4, 1996.

Correspondence to R. H.

BV during treatment ($BV_n$) was estimated from dilution of B-Hb. The fraction of the infused Ringer's acetate solution that remained in blood (%) was calculated, without correction for blood sampling, from the quotient of BV change by the infused volume[4]:

$BV_0$ (litre)=

$$0.03308\ \text{weight (kg)}+0.3561\ \text{length}^3\ \text{(m)}+0.1833$$

$$BV_n=BV_0\times \text{B-Hb}_0\ /\ \text{B-Hb}_n$$

Fluid retained (%)=

$$100\ (BV_n-BV_0)/\text{volume infused}$$

The kinetics of fluid loading were analysed with the aid of the volume-of-fluid-space (VOFS) models, which are based on the assumption that the volume of the fluid space into which the fluid is distributed strives to be maintained in a way similar to one or two elastic balloons. The assumptions on which these kinetic models are based are summarized in figure 1. The equations used for the calculations have been given previously.[5]

Dilution of B-Hb concentration, with a correction made for loss of haemoglobin and fluid resulting from blood sampling, was used to indicate the water load in the VOFS models. As Ringer's solution essentially remains outside the erythrocytes, calculations were based on plasma volume, which was taken to be the product of (1−packed cell volume) and estimated blood volume. During the experiment, packed cell volume was assumed to decrease in proportion to dilution of B-Hb, which is not unrealistic as the infused fluid is isotonic.

The one-fluid space model (VOFS1) uses non-linear least-squares regression to calculate the baseline (target) volume of the expanded fluid space expanded by the infusion ($V$) and the elimination rate constant ($k_r$) and to predict fluid loss (sum of urine excretion and perspiration) during the experiment. Basal fluid loss ($k_b$) was set at 1.0 ml $\text{min}^{-1}$. The two-fluid space model (VOFS2) gives the target volumes of the central and peripheral fluid spaces expanded by the infusion ($V_1$ and $V_2$), rate constant for the diffusion of fluid between these fluid spaces ($k_t$), elimination rate constant ($k_r$) and fluid loss. A partial $F$ test was applied to the residual errors (sum of squares) to select the best model for presentation.[7]

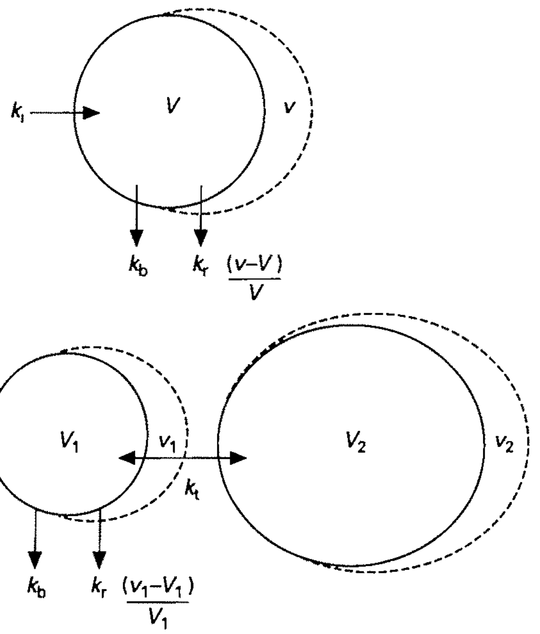

*Figure 1* Schematic diagram of the VOFS1 (upper) and VOFS2 (lower) models. Fluid is infused at a constant rate ($k_i$) and enters a space having the volume ($v$) which changes as a result of fluid leaving the space at a basal rate ($k_b$) and at a controlled rate ($k_r$) proportional to the deviation from the target value ($V$). In VOFS2, a secondary fluid space of volume ($v_2$) which exchanges fluid with the primary fluid space ($v_1$) and the rate of volume equlibration between them is proportional to the difference in the relative deviation from the target value by a constant ($k_t$).

The results are expressed as mean (95% confidence interval). The standard error of the mean (SEM) was used when the data were based on only six experiments. The statistical evaluation also comprised one-way and two-way analyses of variance (ANOVA), repeated-measures ANOVA followed by the Scheffé test, and simple linear regression analysis. $P<0.05$ was considered significant.

## Results

The highest infusion rate (25 ml $\text{kg}^{-1}$ over 15 min) was associated with mild symptoms in all volunteers. Subjects reported a sense of swelling in the hands or face ($n=3$), an abdominal lump ($n=2$), slight dyspnoea ($n=3$), headache ($n=1$) and analgesia around the lips ($n=1$). Occasional complaints of "feeling swollen" were noted during a few other experiments, but these symptoms were very mild.

The fraction of fluid given that remained in blood was higher than the expected 20% during all infusions and for the first 30 min thereafter. Ringer's solution was a more effective plasma expander when it was infused slowly (fig. 2). Blood volume increased by a maximum of 550 ml regardless of how fast the solution was infused (fig. 3).

The dilution–time curves were then analysed according to the one- and two-fluid space models, VOFS1 and VOFS2 (figs 1, 3). Only 10 of the 30 dilution–time curves were more adequately described by VOFS2 (table 1).

When using the most appropriate model for each experiment, two-way ANOVA showed that the size

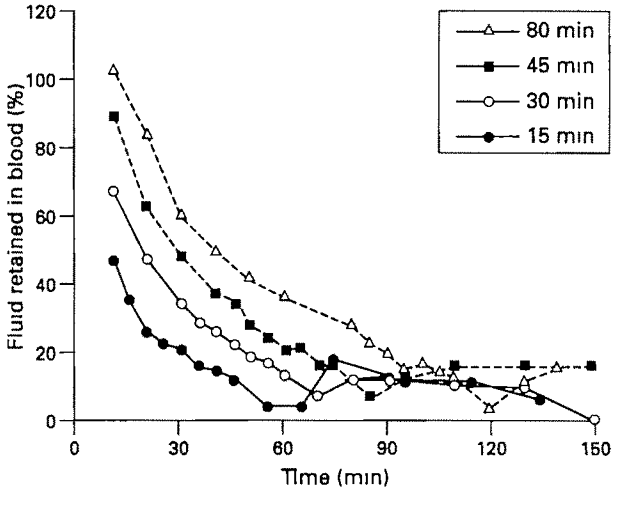

*Figure 2* Fraction of the infused fluid (mean) indicated by haemodilution to be retained in blood during and after infusion of Ringer's acetate solution 25 ml $\text{kg}^{-1}$ in six female volunteers. Time 0=start of infusion.

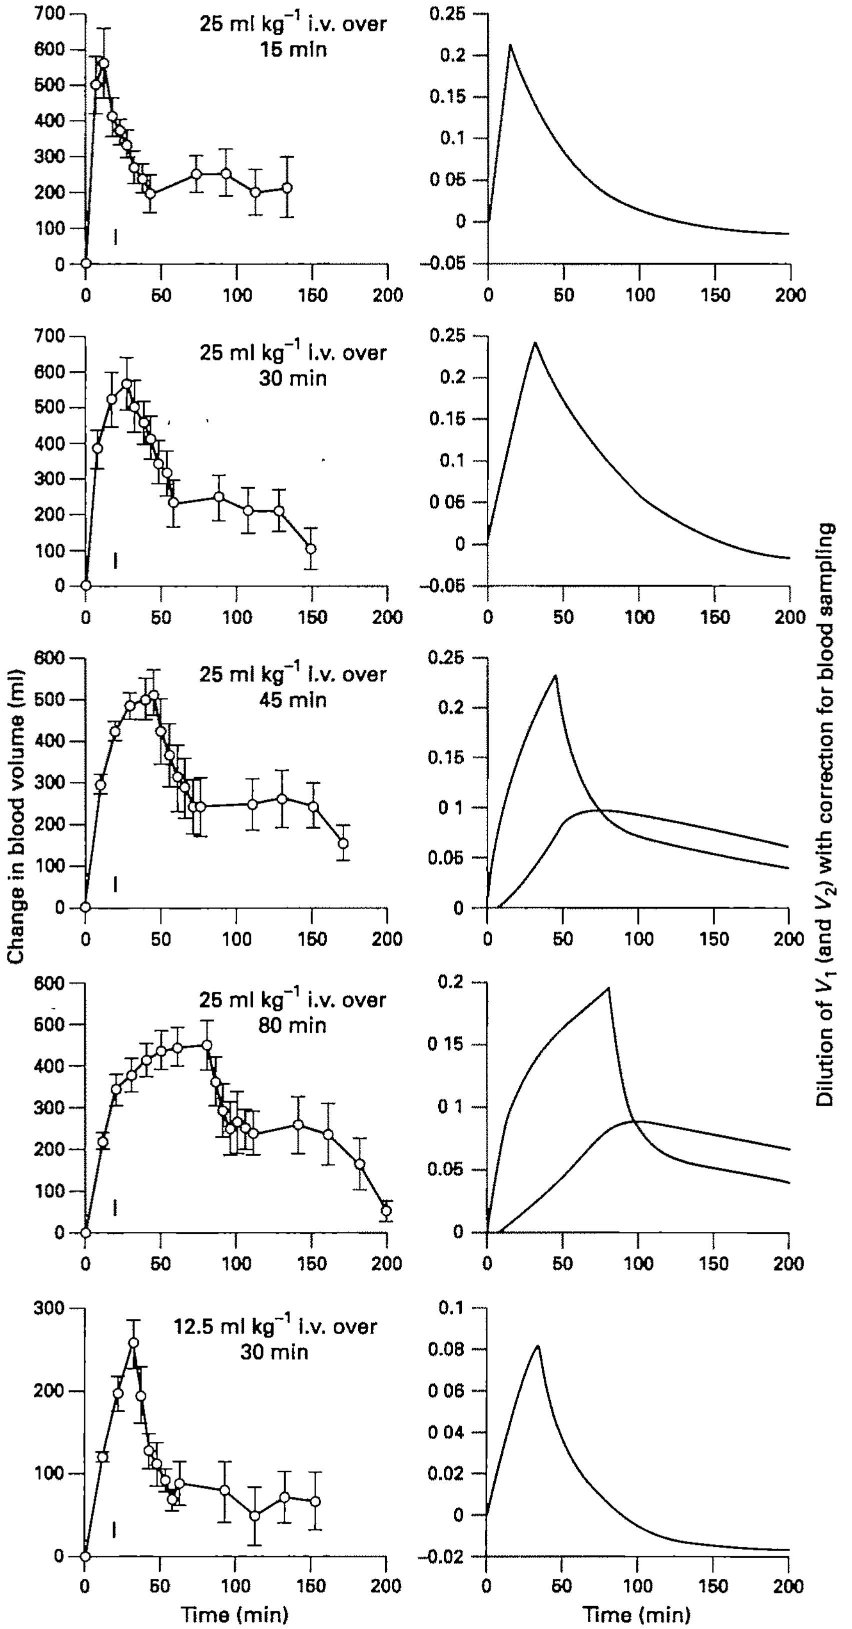

*Figure 3* Change in blood volume (mean, SEM) indicated by haemodilution when Ringer's acetate solution is infused in six female volunteers (left column). The same data with correction for blood sampling analysed by the volume-of-fluid-space models and presented as dilution of the central and (when applicable) peripheral fluid spaces expanded by the infusion (I) (right column).

of the expanded body fluid space ($V$ or $V_1+V_2$) was associated both with the infusion regimen ($P<0.01$) and the subject ($P<0.02$; interaction effect $P<0.04$). These significance levels became stronger when $V$ or $V_1+V_2$ was divided by body weight.

When mean values for each infusion rate were compared, however, it appeared that 12.5 ml kg$^{-1}$ expanded a fluid space of similar size to that expanded by 25 ml kg$^{-1}$ when infused at the low and intermediate rates (mean 4.8 litre (95% confidence

interval 3.8–5.8 litre)) while it was almost twice as large when 25 ml $kg^{-1}$ was given over 15 min ($P<0.05$ by repeated-measures ANOVA) (table 1).

In the 10 experiments in which VOFS2 was optimal, $V_1$ was 2.6 (1.9–3.4) litre and $V_2$ amounted to 6.4 (3.8–9.1) litre. The total expandable volume was significantly larger compared with experiments in which the one-fluid space model was sufficient (table 2).The value of the elimination rate constant $k_r$ differed significantly between subjects (ANOVA $P<0.01$) but not between infusion rates (table 3). For the entire series of experiments, the mean value of $k_r$ was 95 (68–122) ml $min^{-1}$.

Data on urine volume were consistent with results of volume kinetic analysis. Hence, the measured urine volume correlated with the calculated $k_r$ (fig. 4). In the experiments where VOFS2 was optimal, not only $k_r$ and predicted fluid loss, but also urine volume were low (table 2). Some volunteers, notably those who often handled the fluid load according to VOFS1, voided more promptly than others (table 3).

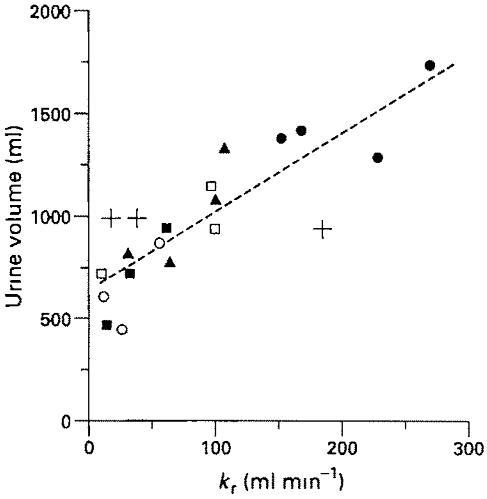

*Figure 4* Relationship between rate constant for dilution-dependent elimination ($k_r$) in the most accurate volume-of-fluid-space model *vs* total urine output when 25 ml $kg^{-1}$ of Ringer's acetate was given by i.v infusion A different symbol is used for each of the six volunteers. $r=0.83$, $P<0.001$

## Discussion

The initial data analysis showed results that differ from the accepted view of how the body handles Ringer's acetate solution. During volume loading, a much greater fraction of the infused fluid was retained in the blood than the 20–25% commonly indicated in medical textbooks. In fact, 20% was not attained until 30 min after infusion, and some of this dilution might have been caused by blood sampling.

The percentage of infused fluid that remained in blood was also dependent on the infusion rate. This finding can be understood better by expressing haemodilution as a change in blood volume, where it becomes apparent that the load–volume relationship should be described by an exponential function rather than by a straight line. The steady-state level corresponded to expansion of blood volume by approximately 550 ml in our resting healthy females. This finding is of interest when Ringer's solution is given very rapidly, such as when volume loading is performed before induction of spinal or extradural anaesthesia. As the volume effect of Ringer's solution is the main purpose of the load, it would seem advisable to slow down an i.v. infusion given very rapidly when steady state is approached. To continue the infusion at a high rate confers no benefit.

These observations suggest that the disposition of a volume load given by i.v. infusion is usually described in oversimplified terms. A mathematical model is needed to analyse more accurately and simulate what happens to the fluid under different conditions. The model used here was developed to describe a dynamic situation. The molecules used to estimate the dilution are already present in the circulation and no radioactive tracer is needed. It is assumed that powerful homeostatic forces act to restore any deviation of fluid spaces to an optimal "target volume" by means of dilution-dependent elimination of fluid. The validity of this view is supported by this study, as elimination of fluid predicted by the model correlated well with urine volume measured.

One- and two-fluid space models were applied to the data. Evidence of expansion of both central and peripheral fluid spaces was found primarily in experiments where a relatively small fraction of the infused volume (mean 48%) was passed during the 2-h follow-up period. In these cases, the volume of the central fluid space was very close to the estimated plasma volume. In most experiments, however, the two-fluid space model offered marginal improvement of the residual error resulting from the curve-fitting procedure. This implies that Ringer's solution, from a kinetic point of view, usually diluted a single well-stirred fluid space. In these experiments, we found more prompt renal excretion of the infused fluid (mean 75%) than in experiments where the two-volume model significantly decreased the residual error. The fact that experiments where the fluid was handled according to VOFS1 were accompanied by both a larger model-predicted fluid loss and a larger urine volume than VOFS2 supports our view that our fluid space models have a physiological basis.

The current view of the disposition of crystalloid solutions such as Ringer's solution is that they are distributed throughout the whole extracellular volume space, which is approximately 12 litre in adult females. However, this study showed that dilution of blood reflected an expandable volume of only 5 litre. This is compatible with the view that Ringer's solution is sequestered in the entire extracellular fluid space while expanding only 40% of it. This finding can probably be explained by a lower compliance for volume expansion in some tissue regions. In fact, the interstitial fluid space is often conceived as a two-phase gel[8]; one phase is difficult to expand because it has a high density of collagen, elastin and glycosaminoglycan, the other phase expands more easily because the density of these macromolecules is lower.

Our results showed that the kinetic model is suitable for further development, as similar results were obtained when the fluid was infused at different rates and also when a different dose was given. The fastest administration of Ringer's solution was the only exception. The large target volume and the symptoms associated with the highest infusion rate probably reflect the fact that areas with lower compliance for accumulation of fluid were also expanded.

To the anaesthetist, the expandable (target) volume is a useful concept as the dilution of the expandable fluid space indicates how much fluid remains in the body during and after i.v. infusion. The volume of the extracellular fluid should apparently not be used for such estimations. Similarly, the rate of urine excretion is the product of $k_r$ and plasma dilution, although we also have to consider a small basal diuresis.

# The lumbar extradural structure changes with increasing age

T. IGARASHI, Y. HIRABAYASHI, R. SHIMIZU, K. SAITOH, H. FUKUDA AND H. MITSUHATA

## Summary

We have examined the extradural space using a flexible extraduroscope in 74 patients undergoing extradural anaesthesia at the L2–3 interspace. Extraduroscopy showed that the extradural space becomes widely patent and the fatty tissue in the extradural space diminishes with increasing age. We postulate that these age-related structural changes may affect the spread of local anaesthetic in the extradural space. (*British Journal of Anaesthesia* 1997; **78**: 149–152).

**Key words**
Anaesthetic techniques, extradural. Measurement techniques, extraduroscopy. Anatomy, extradural space. Age factors.

Many investigators have described the effects of ageing on extradural dose requirements in lumbar extradural anaesthesia.[1–4] Some authors have reported a reduction in lumbar extradural dose requirements with age,[1–3] while others have found that age has little or no effect on the spread of lumbar extradural anaesthesia.[4] However, the reasons for the increase in cephalad spread of extradural analgesia in the elderly have not been investigated thoroughly. Several age-related factors may contribute to the extensive spread of local anaesthetics, especially in the elderly, including arteriosclerosis, decreased neural population[5 6] and increased compliance of the extradural space.[7] The changes in the structure of the extradural space with increasing age may affect cephalad spread of local anaesthetics in the extradural space. Because extraduroscopy can provide a clear view of the lumbar extradural space,[8 9] we used this technique to investigate the effects of age on the structure of the extradural space.

## Patients and methods

This study was approved by our local Ethics Committee and informed consent was obtained from all patients. We examined the lumbar extradural space using a flexible fibrescope in 76 patients undergoing lumbar extradural anaesthesia for a variety of surgical or therapeutic procedures, including hysterectomy, oophorectomy, knee arthroscopy, total knee arthroplasty, total hip arthroplasty, extracorporeal shock-wave lithotripsy, transurethral resection of the prostate and transurethral resection of bladder tumours. Pregnant women and patients with a history of prior extradural anaesthesia, neurological disease or abnormalities of the vertebral column were excluded. Each patient was premedicated with hydroxyzine 25–50 mg. The patient was then placed in the right lateral decubitus position on a horizontal operating table. A 17-gauge Tuohy needle was introduced at the L2–3 interspace using the paramedian technique. The extradural space was identified using the loss-of-resistance method with 5 ml of air. When no cerebrospinal fluid or blood flowed from the needle, the patient underwent examination of the lumbar extradural space with a flexible fibrescope measuring 0.7 mm in diameter (MS-501, Igarashi Ika Kogyo Co., Tokyo, Japan) which was connected to a television monitor system (FV-2000E, Igarashi Ika Kogyo Co., Tokyo, Japan). The extraduroscope was introduced approximately 10 cm in a cephalad direction into the extradural space via the Tuohy needle. No more air was injected after insertion of the extraduroscope in each patient. If paraesthesia or resistance were noted during insertion of the extraduroscope, no attempt was made to advance the extraduroscope through the area of resistance. Consequently, two patients in whom the extraduroscope could not be advanced more than 5 cm cephalad were excluded from analysis. Extraduroscopic findings were recorded continuously on a video recorder during the examination in each patient. After extraduroscopic examination, an extradural catheter (external diameter 0.85 mm; B. Brown, Bethlehem PA, USA) was inserted 5 cm cephalad into the extradural space and the patient was then placed in the supine position. All procedures were performed by the same anaesthetist. Patients received local anaesthetic via the catheter during the planned therapeutic or surgical procedure, with or without general anaesthesia, used in combination.

The extraduroscopic findings in our 74 patients were analysed by two independent investigators who were blinded to the patients' medical histories. Extraduroscopic findings were divided into five

Correspondence to T. I

categories for analysis: patency of the extradural space, amount of fatty tissue, amount of fibrous connective tissue, degree of vascularity and blood vessel trauma at the tip of the Tuohy needle. The patency of the extradural space was scored using the following grading system: 1=extremely narrow, 2=patent and 3=widely patent. The other four findings were scored using the following grading system: 1=none, 2=moderate and 3=extensive. When a discrepancy between two observers in each finding was noted, this difference was resolved by a third experienced investigator to reach consensus.

Statistical analyses were carried out using a statistical software package (StatView V4.02, Abacus Concepts, CA, USA) on a personal computer (Macintosh Quadra 650, Apple Computer, Inc., CA, USA). The relationship between age and each extraduroscopic finding was analysed by Spearman's correlation coefficient by rank. Mean age in each grade of the extraduroscopic finding was analysed by the Kruskal–Wallis test and Mann–Whitney's *U* test. $P<0.05$ was considered statistically significant.

## Results

Mean age, height and weight were 51 (range 23–81) yr, 157 (SD 8) cm and 56 (9) kg, respectively (table 1).

Extraduroscopic examination (table 2) revealed significant correlations between age and the patency of the extradural space ($\rho=0.33$, $P=0.02$) and the amount of fatty tissue ($\rho=-0.28$, $P=0.004$). Amount of fibrous connective tissue, degree of vascularity and blood vessel trauma were not related to age. None of the extraduroscopic findings in this study showed correlations with height, weight, body mass index or body surface area. With regard to patency, mean age was significantly higher in patients who scored 3 than in patients who scored 1 or 2 (table 3). With regard to the amount of fatty tissue, mean age was significantly lower in patients who scored 3 than in patients who scored 1 or 2. Blood vessel trauma at the site of the Tuohy needle in the extradural space was observed in 21 (28%) patients, all of whom were scored as grade 2, on the fatty tissue, dura mater or periosteal layer. There was no productive or massive bleeding which occupied the extradural space. None of the blood vessels was injured by the extraduroscope at a site distant from the Tuohy needle.

Figure 1 shows typical extraduroscopic findings in elderly patients. The extradural space in a 77-yr-old man was observed as a widely patent canal (fig. 1A). The grey membranous structure on the left was identified as the dura mater and the right part of the canal was identified as the periosteal layer. Fibrous

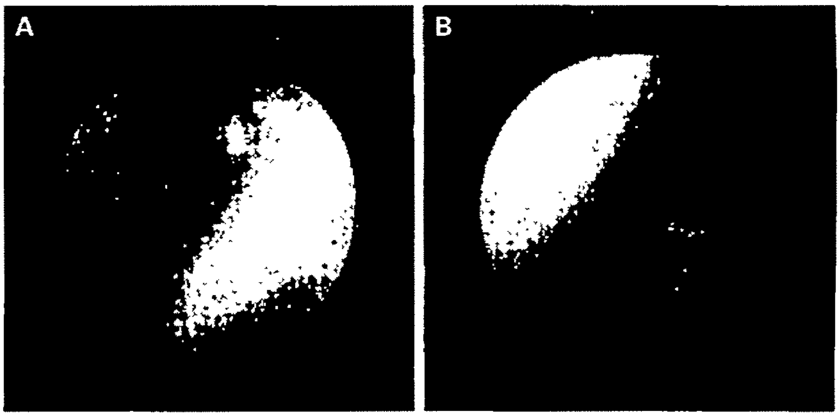

*Figure 1* Photographs obtained via the extraduroscope in a 77-yr-old man The extradural space is observed as a widely patent canal (A). Fatty tissue is seen to have been torn from the dura mater by the air injected into the extradural space as the extraduroscope is advanced (B) Fibrous connective tissues extend across the patent canal. In this patient, the patency of the extradural space, amount of fatty tissue, amount of fibrous connective tissue and degree of vascularity were scored as 3, 2, 3 and 1, respectively

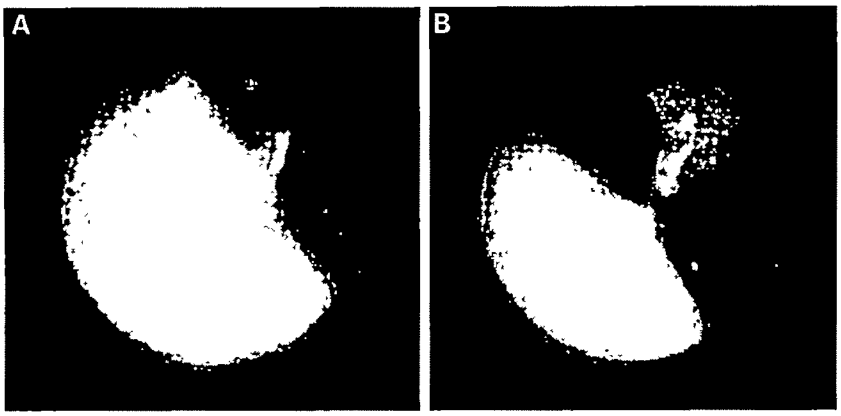

*Figure 2* Photographs obtained via the extraduroscope in a 26-yr-old man. The extradural canal appears to be extremely narrow because of the presence of a large amount of fatty tissue (A) The fatty tissue is seen to be under tension and tightly adherent to the dura mater or the periosteal layer beyond the fibrous connective tissue (B). In this patient, the patency of the extradural space, amount of fatty tissue, amount of fibrous connective tissue and degree of vascularity were scored as 2, 3, 3 and 2, respectively.

connective tissue was seen between the dura mater and the periosteal layer. In the same patient, fatty tissue was observed in the extradural space as the extraduroscope was advanced (fig. 1B). The left part of the canal was identified as the dura mater with its associated blood vessels and the right part of the canal was identified as fatty tissue associated with the periosteal layer. In this region, fatty tissue was seen to have been torn away from the dura mater by the air injected into the extradural space and fibrous connective tissue was seen extending across the patent canal. In this patient, patency of the extradural space, amount of fatty tissue, amount of fibrous connective tissue and degree of vascularity were scored as 3, 2, 3 and 1, respectively.

Figure 2 shows typical extraduroscopic findings in young patients. A narrow extradural space created by the injected air is seen in the right, lower part of the photograph obtained in a 26-yr-old man (fig. 2A). The left part of the canal appears as a white membrane with associated blood vessels and was identified as the dura mater. The outer area on the right side of the photograph was identified as fatty tissue with blood vessels. The extradural canal appeared to be very short and narrow because of the presence of a large amount of fatty tissue (fig. 2B). The fatty tissue was seen to be under tension and tightly adherent to the dura mater or the periosteal layer beyond the fibrous connective tissue. In this patient, the patency of the extradural space, amount of fatty tissue, amount of fibrous connective tissue and degree of vascularity were scored as 2, 3, 3 and 2, respectively.

We encountered no accidental dural punctures and observed no signs of persistent neurological injury in any of our patients.

## Discussion

In this study, extraduroscopic examination revealed that the amount of fatty tissue was reduced and the extradural space became widely patent with increasing age. We postulate that the amount of fatty tissue in the lumbar extradural space may play an important role in determining the patency of the extradural space, thereby affecting the longitudinal spread of anaesthetic solutions in the elderly.[1-3]

We found that the patency of the extradural space, after injection of 5 ml of air into the extradural space, became greater with increasing age. Our results on the patency of the extradural space may be related to the fact that the compliance of the extradural space increases with advancing age.[7]

Another extraduroscopic finding was that the amount of fatty tissue was related inversely to increasing age. This may be one reason for the changes in patency of the extradural space in the elderly. As the fatty tissue degenerates with advancing age, the extradural space becomes more compliant, resulting in the observed changes in the patency of the extradural space. In addition, our results demonstrated that the extradural space in young patients was packed tightly with rigid fat[10] and showed low compliance.

Connective tissues other than fatty tissue were observed as strands or membranes in the extradural space and were not found to be related to age. These connective tissues are found between the fatty tissue, dura mater and periosteal layer. Although these connective tissues were thought to be important factors related to compliance of the extradural space, we did not find age-related differences in fibrous connective tissues. Because these fibrous connective tissues were more fragile than the fatty tissue, they may have been stretched and broken by the air introduced into the extradural space. If the amount of air introduced into the extradural space was more or less than 5 ml, it may be possible to demonstrate statistically significant changes in the amount of fibrous connective tissue with increasing age.

In assessing the results of this study, we must consider several factors that may have affected our results. The extradural space was observed after introducing a small amount of air. The extradural space is sometimes described as a potential space, rather than a true cavity.[9 11 12] The introduction of air may therefore have affected our extraduroscopic findings, expanding the extradural space and stretching the connective tissues. However, in our study, all patients received identical extradural punctures and the effects of air introduced into the extradural space should have been comparable in all cases. Therefore, we believe that this factor had no influence on our comparative findings.

We observed fatty tissue in a segmental distribution in the extradural space as the extraduroscope was advanced in a cephalad direction. That the extradural fatty tissue is divided into segments by interposed laminae in the lower thoracic and lumbar regions has been demonstrated by sagittal midline magnetic resonance imaging.[13] In this study, extradural structures were observed mainly from the point where the fatty tissue ceased to exist. We did not divide our extraduroscopic findings into two separate categories based on the presence or absence of fatty tissue because the patency of the extradural space tended to be similar regardless of the presence of fatty tissue.

In the lower thoracic and lumbar segments, it has been suggested that the extradural space is divided transversely into three compartments: anterior, dorsal and dorsolateral.[14] Unfortunately, we were not able to determine which of the three compartments of the extradural space was observed in this study. In some cases the extraduroscopic findings showed the compartments of the extradural space to be incompletely separated by thin and fragile membranes. Our extraduroscopic procedures were performed by the same anaesthetist and the tip of the Tuohy needle was introduced into the extradural space as precisely as possible in the midline. However, differences between the three compartments in terms of extraduroscopic findings have not yet been clarified, and these differences may have affected our findings.

Several technical problems were encountered during the procedure. Nerve root irritation during insertion of the extraduroscope may be related to technical problems with extradural puncture. The cord or nerve roots may be compressed during insertion of the extraduroscope, which is more rigid than the extradural catheter. Although extradural punctures were performed using the same procedures employing the paramedian technique, the angle of the needle relative to the dorsal plane of the skin may have varied from patient to patient. We postulate that the greater the cephalad angle of the needle relative to the dorsal plane of the skin, the lower the incidence of nerve root irritation. Indeed, in patients who experienced nerve root irritation during insertion of the extraduroscope, repeat attempts with a greater needle angle made it possible to insert the extraduroscope into the extradural space without eliciting nerve root irritation. Therefore, the cephalad angle of the Tuohy needle relative to the dorsal plane of the skin appears to be a very important consideration in performing extraduroscopy without nerve root irritation. Although none of our patients who experienced nerve root irritation suffered permanent neurological injury, care should be taken not to damage the nerve roots or cord when irritation is encountered during extraduroscopic examinations.

We observed blood vessel trauma induced by the introduction of the Tuohy needle into the extradural space in approximately 25% of all patients. Arteriosclerosis is seen frequently in the elderly, and the incidence of blood vessel trauma might therefore be expected to increase with advancing age. However, the incidence of blood vessel trauma by the tip of Tuohy needle was not found to be related to age. Blood vessel trauma was observed on the fatty tissue, dura mater and periosteal layer by the tip of Tuohy needle in the extradural space. However, we observed no productive or massive bleeding which was filled with the extradural space. Although we sometimes experience intravascular migration of an extradural catheter in clinical practice,[15 16] it remains unknown in which vessels the extradural catheter is misplaced.

# Do anxiety or hypocapnia predispose to apnoea after induction of anaesthesia?†

G. B. DRUMMOND AND N. M. M. EL-FARHAN

## Summary

We have studied the incidence of apnoea after induction of anaesthesia in patients allocated randomly to receive a standardized dose of either propofol or etomidate. We measured anxiety before operation with a standard questionnaire and end-tidal carbon dioxide concentration from a mask during breathing 35% oxygen, before induction of anaesthesia. Respiration was measured by pneumotachograph and impedance pneumograph. There was no significant relationship between anxiety score and end-tidal carbon dioxide concentration before operation. Patients given propofol ($n=26$) received a median dose of 157 mg over 70 s, and 17 became apnoeic (median duration 24 s, quartile values 0, 76). Apnoea was more severe in patients whose preoperative end-tidal carbon dioxide value was less than the median value (median duration of apnoea 61 s compared with 10 s; $P<0.05$). Patients given etomidate ($n=25$) received 16.2 mg in 57 s, which was a significantly smaller fraction of the calculated dose requirement, and had significantly less apnoea: eight became apnoeic (median duration 0 s, quartile values 0, 23 s). There was no relationship between apnoea and end-tidal carbon dioxide concentration in these patients. Anxiety did not relate to the incidence of apnoea with either induction agent. We conclude that apnoea after induction of anaesthesia with propofol is more likely if hypocapnia is present but we could not relate apnoea or hypocapnia to anxiety in the ward before operation. (*Br. J. Anaesth.* 1997; **78**: 153–156)

**Key words**
Complications, apnoea. Ventilation, apnoea. Anaesthetics i.v., propofol. Anaesthetics i.v., etomidate. Carbon dioxide, hypocapnia. Psychological responses

Apnoea is frequent after introduction of anaesthesia with i.v. agents, and more likely with propofol than with other agents.[1] Propofol depresses the ventilatory response to hypoxia,[2] but in some circumstances apnoea can also be caused by a combination of hypocapnia and sedation: for example it can be caused by voluntary hyperventilation in association with nitrous oxide inhalation.[3] Patients receiving preoxygenation may be encouraged to hyperventilate or may hyperventilate because they are anxious, and hence become hypocapnic. We tested the hypothesis that anxiety and hypocapnia before operation would predispose to apnoea and studied the effects of two agents that are known for their different effects on respiration, propofol which causes more apnoea[1] and etomidate less, in comparison with other agents.[4]

## Patients and methods

After obtained local Ethics Committee approval and written informed consent, we studied women undergoing gynaecological procedures under general anaesthesia as day patients. We excluded patients who were more than 40% of their expected weight, had clinically significant cardiorespiratory disease or who were receiving medication that could alter anxiety or respiratory responses. We did not exclude those who were in early pregnancy. Between 30 min and 2 h before the anaesthetic, we assessed each patient's anxiety using a standardized questionnaire consisting of 12 statements, with the response to each question graded from "not at all" to "extremely" in five categories. The statements were both positive (e.g. "I feel I can cope") and negative (e.g. "I want to escape from here") so that the categorical response required more careful thought. The categories were marked from 1 (least anxious) to 5 (most anxious) and summed so that the score was between 12 (least anxious) and 60 (most anxious).

To allow anaesthetic induction to be as standard as possible, and compare the induction agents, we estimated the induction dose required for each patient so that by giving this estimated dose at a steady rate each patient should receive an induction dose of the agent over the same time. We noted height and weight of the patients and measured skinfold thickness at the biceps, triceps, subscapular region and suprailiac regions with standard methods to allow estimation of lean body mass.[5] Using age

and lean body mass we predicted the clinical induction dose of thiopentone using regression data from Avram and co-workers,[6] with the equation:

$$\text{dose (mg)} = 282 + 1.6 \text{ lean mass (kg)} - 1.78 \text{ age (yr)}$$

From this thiopentone dose, the equivalent induction dose for propofol was obtained using a relative potency of 0.625.[7] For etomidate we used a ratio of 0.038. These doses of propofol and etomidate, given over 100 s, provide a median induction dose for similar patients (unpublished data). We diluted 1.4 times the estimated induction dose in 40 ml, with 0.9% sodium chloride containing 1 ml of 0.5% lignocaine solution. At induction of anaesthesia this was given as 0.4 ml $s^{-1}$ so that a median induction dose was given in approximately 70 s and further agent was available in the syringe if necessary for patients who required more than the median amount. Randomization was with sealed envelopes in blocks of 20.

No premedication was given. When the patient came to the anaesthetic room an i.v. cannula was inserted in one hand and a two-electrode impedance pneumograph was attached using disposable silver–silver chloride ECG electrodes placed on each side of the chest in the midaxillary line at the level of the nipples. Standard electrodes for ECG monitoring, non-invasive arterial pressure cuff and a finger probe pulse oximeter were attached. No arterial pressure measurements were made during the measurements. A well fitting mask, with an inflatable pneumatic rim (Respironics), was applied to the face and the patient's head extended to allow a clear airway to be maintained. The mask was fitted with a sampling port which was connected to a sidestream capnometer (Datex Oxycap), calibrated at the start and end of the study with the manufacturer's standard gas. The mask was connected to a pneumotachograph and a T-piece system supplied with a Venturi oxygen device that gave 35% oxygen: the other limb of the T-piece was open to room air. Pneumotachograph pressure was measured with a differential transducer (Furness micromanometer) and the flow and pneumograph signals passed to a laptop computer for digitizing and storage using a commercial logging and analysis package (Oxcams Cardas). The patient was then given a solid steel cylinder, 10 cm long and 1.25 cm in diameter, to hold between the thumb and first finger of the hand that did not have the i.v. cannula, and asked to hold it without letting it drop.

After the patient had been breathing from the system for approximately 2 min she was asked to exhale to obtain a good expiratory plateau value for end-tidal carbon dioxide concentration and this value was noted. When respiration had become regular again and satisfactory signals of flow and pneumograph were present on the computer display, the induction agent was injected at 0.4 ml $s^{-1}$ until the patient dropped the weight, when injection stopped and the time was recorded on the computer. If there was no flow signal, then the mask was kept in place until respiration re-started. The impedance signal was observed to see if there was obstructive apnoea, with absent flow but continued chest wall movements, in which case the head and neck were moved to obtain a clear airway. The mask was kept in place until respiration re-started and then removed to allow the anaesthetic to be continued. The digitized record was replayed later. Apnoea was defined as the absence of inspiratory flow for more than 10 s: if apnoea occurred, the times of cessation and restarting respiration were noted. Summary values for apnoea duration in the groups were calculated using zero values for those subjects who did not stop breathing.

After the patient had returned to the ward, another measurement was made of end-tidal carbon dioxide concentration between 1 and 2 h after the procedure. Analgesics used in the operative and postoperative periods, which were not standardized, were noted.

The relationship between the incidence and duration of apnoea, preoperative anxiety score, end-tidal carbon dioxide concentration and induction agent was investigated with scatter plots. The incidence of apnoea was tested using the chi-square test and the severity of apnoea compared between agents, and within subgroups, using the Mann–Whitney test, with Minitab version 8.2 running in MS-DOS version 6.2. $P<0.05$ was taken as significant. The distribution of many of the variable values was not normal and they are summarized as median (interquartile) values.

## Results

Of 56 patients who agreed to the study, 54 were allocated randomly to treatment (six were asked and declined to take part). Patient details are shown in table 1. There were no differences between groups in age, height, weight, percentage body fat, preoperative anxiety scores or end-tidal carbon dioxide values.

The median dose of propofol given was 158 (140,182) mg and induction time was 67 (59, 77) s. This was significantly greater than the induction time for the etomidate group (57 (48, 64) s; dose administered 16 (14.5, 17.6) mg). Because the agents were given at a rate set by the predicted dose for each patient, the different induction times indicate a significant difference between the proportion

*Table 1* Patient details (median (quartile values) or numbers)

| | Propofol group | Etomidate group |
|---|---|---|
| *n* | 26 | 25 |
| Age (yr) | 31 (28–39) | 34 (26–41) |
| Height (cm) | 160 (158–163) | 163 (158–169) |
| Weight (kg) | 64 (60–70) | 64 (57–74) |
| % Body fat | 37 (34–40) | 36 (32–40) |
| Anxiety score | 23 (18–29) | 25 (19–29) |
| Preoperative end-tidal $CO_2$ (kPa) | 4.4 (4.3–4.7) | 4.8 (4.5–5.3) |
| Dose prediction (mg) | 181 (173–187) | 22 (21–23) |
| Dose administered (mg) | 158 (141–182) | 16 (14.5–17.6) |
| Dose given/dose predicted | 0.87 (0.78–1.05) | 0.75 (0.66–0.83) |
| Induction time (s) | 67 (60–77) | 57 (48–64) |
| Apnoea (*n*) | 17 | 8 |
| Apnoea (s) (all patients) | 24 (0–77) | 0 (0–23) |
| Postoperative end-tidal $CO_2$ (kPa) | 4.7 (4.1–5.5) | 4.8 (4.5–5.3) |

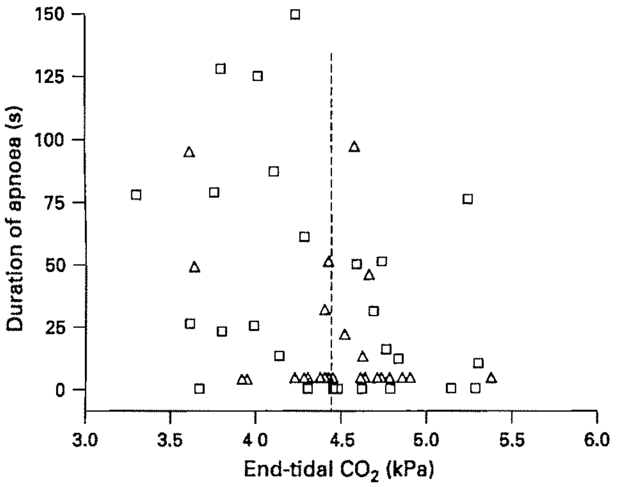

*Figure 1* Relationship between apnoea, taken as absence of breathing for more than 10 s, and preoperative end-tidal carbon dioxide ($CO_2$) values in patients receiving propofol (□) or etomidate (△) (these symbols are offset upward to improve clarity).

of predicted dose given; for propofol 0.87 (0.77–1.05) and for etomidate 0.75 (0.66, 0.83) ($P<0.01$).

There was no relationship between preoperative anxiety score and end-tidal carbon dioxide values before operation.

There was a significant difference in the incidence and duration of apnoeas in patients who received propofol (17 apnoeas, median duration of apnoea 24 (0, 77) s) compared with the etomidate group (eight apnoeas, median duration 0 (0, 23) s) ($P<0.05$). Figure 1 shows the relationship between apnoea duration and preoperative end-tidal carbon dioxide values. Because the relationship between these values was not linear, we classified patients into those whose preoperative end-tidal carbon dioxide concentration was greater, and less than or equal to the median: we then compared duration of apnoea in the low and high end-tidal carbon dioxide groups. In patients who received propofol, apnoea was significantly greater in the 13 patients who had smaller carbon dioxide values (61, 18–146 s) compared with those who had larger carbon dioxide values (10, 0–40 s) ($P=0.0167$). This relationship was not found in patients who received etomidate (0, 0–41 and 0, 0–14 s for the two groups, which contained 12 and 13 patients, respectively) ($P=0.767$).

Most patients received a variety of analgesics, including long- and short-acting opioids, either during or after the procedures, and no relationship was found between postoperative end-tidal carbon dioxide values or changes in values before and after operation, with any other variable. Postoperative values were obtained 25–95 min after recovery from anaesthesia. One value could not be obtained for technical reasons, but for the remainder, median end-tidal carbon dioxide values after operation were 4.8 (4.2–5.3) kPa whereas they were 4.4 (4.1–4.7) kPa before the procedure ($P<0.01$). There was no difference in carbon dioxide values after operation in patients who received propofol and those who received etomidate.

## Discussion

Apnoea is less frequent when propofol is given slowly[8] whereas slow injection of other induction agents does not seem to affect the incidence of apnoea.[4] As we wished to compare the two agents, we used a method that should have allowed us to give the induction dose of both agents in the same time. We used estimates of potency derived in the same type of patient, where the induction dose was given over approximately 80 s. Injection time was decreased slightly in this study to approximately 70 s. We did so to more closely simulate the rate of injection that is used commonly in clinical practice and we wished to allow apnoea to become apparent so that we could investigate the relevant factors associated with it. However, the estimates were greater than necessary, significantly so for etomidate, and therefore the injection times were significantly different. However, the differences were small (12% of the dose estimate) and we do not consider that the difference in time taken for injection (57 *vs* 66 s) affected the comparability of the effects of the agents, particularly as both were given to the same end-point.

We used preoxygenation to avoid the confounding effect of hypoxia, which may contribute to restoration of breathing after apnoea has occurred, but avoided using 100% oxygen because it may alter cerebral blood flow and thus affect respiration.[9] Although propofol depresses the ventilatory response to hypoxia[2 10] there are no definitive reports that preoxygenation can prolong the duration of apnoea caused by propofol, and a decrease in ventilation in response to hyperoxia can be found to persist during propofol anaesthesia.[11] The depressant effects of propofol on ventilatory responses to carbon dioxide are also significant and prolonged.[12] Consequently, our finding that propofol caused apnoea, and etomidate did not, was expected, and we have concentrated on the features of the apnoea in this group of patients.

We have used the questionnaire for anxiety in previous studies and found it satisfactory. As suggested by Millar and co-workers, it describes anxiety in terms that most patients find familiar.[13] These workers found three different methods of measurement of equivalent efficacy, and we consider that our questionnaire is similar. However, we found that anxiety measured in this way could not be related to preoperative end-tidal carbon dioxide concentration or to the incidence of apnoea. Anxiety may have increased between completing the form and starting the induction of anaesthesia, to a different degree in different subjects, thus invalidating this measure as a test of the initial hypothesis.

We measured end-tidal carbon dioxide using a mask, which is less accurate than the use of a mouthpiece, but we were able to assess the size of the expired breath and are confident that measurements in these relatively young and healthy subjects were a good index of $Pa_{CO_2}$. However, we did not control or standardize analgesic administration (which varied considerably according to the procedure undertaken) and hence are not confident that the values of end-tidal carbon dioxide that we obtained after operation were of value, although we had hoped that the change from before to after operation could have been an index of those patients who were hypocapnic before the procedure, by relating the carbon dioxide value to their resting value.

There was no clear linear relationship between preoperative carbon dioxide concentration and apnoea. However, it was evident that hypocapnia was associated with more frequent and prolonged apnoea after propofol, whereas the less frequent apnoeas after etomidate could not be related to hypocapnia. We propose that the drive to respiration from wakefulness and anxiety have reduced arterial and brain carbon dioxide values well below those necessary to stimulate respiration, and after loss of consciousness these values have to increase sufficiently before regular respiration starts again. We attempted to minimize upset to the patient from the use of the mask, and it is likely that the effects were similar to a routine anaesthetic, and consequently we are confident that our findings reflect the clinical situation. Although other manoeuvres have been suggested as helpful in reducing the likelihood of apnoea after induction of anaesthesia, such as slow administration of propofol and vital capacity breaths before induction,[14] we suggest that manoeuvres to limit the development of hypocapnia may be useful if apnoea is troublesome.

# Comparison of induction and recovery between sevoflurane and halothane supplementation of anaesthesia in children undergoing outpatient dental extractions

S. A. ARIFFIN, J. A. WHYTE, A. F. MALINS AND G. M. COOPER

## Summary

We have compared sevoflurane and halothane in a double-blind controlled study for supplementation of nitrous oxide and oxygen anaesthesia in 80 children undergoing dental extraction as outpatients. Induction of anaesthesia was more rapid in those who received sevoflurane compared with those who received halothane (89 s compared with 127 s for loss of eyelash reflex). In both groups, mean duration of administration of anaesthesia was less than 4 min. Those who received sevoflurane were slower to awaken (167 s compared with 102 s), although discharge times from hospital were similar. The incidence of complications during induction and maintenance was low in both groups and return to normal appetite and activity occurred in the majority of children on the same day. More children who received halothane suffered nausea after leaving hospital. We conclude that sevoflurane is a suitable alternative to halothane, with more rapid induction of anaesthesia, but in these short procedures, awakening time was slower than after halothane. (*Br. J. Anaesth.* 1997; **78**: 157–159)

**Key words**

Anaesthesia, paediatrics. Anaesthetics volatile, halothane. Anaesthetics volatile, sevoflurane. Surgery, dental. Children.

The majority of patients who require anaesthesia for dental extraction are children who are unwilling to accept needles and request inhalation induction. Rapid induction and swift recovery are desirable characteristics of anaesthesia for these short procedures which are performed on an outpatient basis. The low blood:gas partition coefficient of sevoflurane[1] and its lack of airway irritability suggest that it has many features of the ideal inhalation agent[2] and that it may be preferable to halothane for short procedures in children.[3–9] Although more rapid recovery from anaesthesia with less soluble agents may be anticipated, a previous study[10] comparing isoflurane with halothane did not show this to be the case in paediatric dental outpatients.

We have compared induction, maintenance and recovery from brief anaesthesia when either sevoflurane or halothane was the sole supplement to anaesthesia with nitrous oxide and oxygen in unpremedicated children undergoing outpatient dental extractions.

## Patients and methods

After obtaining local Ethics Committee approval and written parental consent, we studied 80 healthy children, not receiving any medication, aged 5–12 yr, undergoing dental extraction as outpatients for which inhalation induction of anaesthesia was requested. Children were allocated randomly to one of two groups to receive either sevoflurane or halothane supplementation of 66% nitrous oxide in oxygen, in approximately equipotent inspired concentrations.[2 11]

No premedication was used. Induction of anaesthesia was by inhalation of 2% sevoflurane or 0.75% halothane and 66% nitrous oxide in oxygen for five breaths before maintenance with 4% sevoflurane or 1.5% halothane until the teeth had been extracted. The vaporizer settings were controlled behind a screen by a second anaesthetist, such that the administering anaesthetist was unaware which volatile agent was being given. Anaesthesia was given with the child sitting in the dental chair, via a close-fitting nasal mask using a Mapleson A system with active scavenging. Routine digital pulse oximetry was used to monitor oxygen saturation. The times at which loss of eyelash reflex occurred and at which jaw tone became sufficiently relaxed to permit insertion of a dental gag and mouth pack were recorded. These times and the presence or absence of complications were assessed by the administering anaesthetist.

Recovery from anaesthesia was assessed by the time taken from discontinuation of anaesthesia until the child opened his/her eyes. In the recovery room, experienced recovery nurses, who were also unaware of the agent used, recorded when the child was able to stand unaided without swaying and was able to walk in a straight line. The presence or absence of nausea, vomiting, shivering, headache and coughing

Correspondence to G M. C

in recovery and when the child was ready to leave hospital were also recorded.

Return to normal activity and normal appetite in addition to the presence or absence of headache, nausea, vomiting, dizziness, muscle aches and bad dreams were sought using a questionnaire completed and returned by the accompanying parent.

Statistical comparisons of patient characteristics, operative details, and induction and recovery times were made by unpaired Student's *t* test. Complications during induction of anaesthesia, while recovering in hospital and after going home were compared by chi-square test.

## Results

Both groups were comparable in age, weight, number of teeth extracted, duration of administration of anaesthesia and duration of surgery (table 1). Induction of anaesthesia was significantly shorter ($P<0.05$) in children who received sevoflurane in whom the mean time to loss of eyelash reflex was 89 s compared with 127 s in those who received halothane (table 1). There were notably few airway complications during induction and maintenance of anaesthesia (table 2). Although movement was noted in some children, this did not interfere with dental extraction.

Mean duration of administration of anaesthesia was similar in both groups and was less than 4 min (table 1). While those children who received halothane awakened significantly more rapidly than those who received sevoflurane, there was no difference in the times taken to stand without swaying and to walk in a straight line unaided. The times at which the children were considered ready for discharge from hospital were similar in both groups.

| Next day | 8 | 12 |
| Later | 1 | 0 |

Headache and nausea were the most frequent complications in the recovery room: there was no significant difference between groups (table 3). After discharge from hospital parents returned questionnaires for 31 children who received sevoflurane and 32 who received halothane. Significantly more children who received halothane suffered nausea after leaving hospital (table 4). The majority of children returned to normal activity and appetite the same day and all except one in each group did so by the following day (table 5).

## Discussion

The most surprising finding was that despite more rapid induction of anaesthesia with sevoflurane, the time to awaken was faster with halothane. This was similar to the finding in a previous study comparing isoflurane and halothane under almost identical conditions.[10] The more rapid induction of anaesthesia with sevoflurane (and isoflurane) is expected from published wash-in curves[12] and is confirmed in clinical practice.[3–9] However, published wash-out curves[12] and initial clinical experience[3–6 8 13] also suggest that early recovery is more rapid after sevoflurane than after halothane. The important difference in our study was the short duration of anaesthesia. At the end of 4 min, children who received sevoflurane were nearer the stage of full saturation than those who received halothane. Consequently, when surgery ended and sevoflurane was discontinued, serum concentrations decreased mainly by excretion whereas for those receiving halothane, considerable scope was available for serum concentrations to decrease by redistribution, in addition to excretion through the lungs. Thus because the volatile agents were discontinued before a state of "plateau" pharmacokinetics had been reached, the relative behaviour of the usually published wash-out curves cannot be expected.

The potentially distressing time for children is during induction of anaesthesia and the fact that sevoflurane reduced the time to loss of eyelash reflex by an average of 38 s (or by 30%) was both statistically and clinically significant. The study was designed to make a direct comparison between sevoflurane and halothane and we accept that higher initial concentrations of sevoflurane or other techniques of induction can further reduce induction times.[14] The absence of respiratory complications on induction is also important to the acceptability of volatile agents for inhalation induction, and both sevoflurane and halothane were well accepted and non-irritant. Notably, there were no episodes of hypoxia.

As in a previous study,[10] the majority of children resumed normal activity and appetite on the same day. This reflects rapid recovery from anaesthesia and minimal effects of minor surgery. The incidence of nausea after leaving hospital was greater in those children who received halothane, but if the results are combined for those who suffered nausea while still in hospital, there was no difference between the agents. The irritant effects of swallowed blood after dental extraction may not make this study comparable with others in children undergoing other types of surgery.

In summary, we found sevoflurane to be a suitable alternative to halothane for dental outpatient surgery in children, having a significant advantage in the speed of induction. The slower awakening time after sevoflurane did not delay discharge from hospital. Recovery to normal activity and appetite was good, and there was a low incidence of adverse effects during induction, maintenance and recovery.

J. M. PEUTRELL, K. HOLDER AND M. GREGORY

## Summary

The maximum recommended dose for extradural infusions of bupivacaine in children older than 1 month is 0.5 mg kg$^{-1}$ h$^{-1}$ but there are few specific reports of the associated blood concentrations during infusions in babies. Toxic symptoms can occur in children at plasma concentrations of bupivacaine as low as 2 μg ml$^{-1}$. We attempted to measure venous plasma concentrations of total and free bupivacaine in babies aged 3–12 months during extradural infusions given at a rate commonly used in our hospital. We studied eight babies (mean age 33 weeks; mean weight 7.8 kg). After a mean initial dose of 1.2 mg kg$^{-1}$ (range 1.1–1.3 mg kg$^{-1}$), bupivacaine was infused at a mean rate of 0.38 (0.36–0.39) mg kg$^{-1}$ h$^{-1}$ for a mean of 31 (4–44) h. Blood was obtained at 4, 8, 16, 24, 32 and 40 h after starting the infusion and plasma separated by centrifugation. Total plasma bupivacaine concentration was measured using high pressure liquid chromatography (HPLC). Plasma concentrations of total bupivacaine were mostly less than 2 μg ml$^{-1}$. One baby had a concentration of 2.02 μg ml$^{-1}$ at 32 h and showed clear evidence of accumulation of bupivacaine. Babies can accumulate bupivacaine and achieve plasma concentrations above the threshold for toxic side effects, despite infusion rates below the currently accepted maximum. The sample size in our study was small but we believe an extradural infusion rate of 0.375 mg kg$^{-1}$ h$^{-1}$ is probably an absolute maximum for babies younger than 12 months. (*Br. J. Anaesth.* 1997; **78**: 160–162)

**Key words**

The maximum recommended rate for extradural infusion of bupivacaine in children older than 1 month is 0.5 mg kg$^{-1}$ h$^{-1}$.[1] At the time of this editorial there were no specific reports of blood concentrations of bupivacaine during extradural infusions in babies younger than 12 months. The aim of our study was to measure venous plasma concentrations of both total and free bupivacaine during continuous extradural infusion of bupivacaine 0.375 mg kg$^{-1}$ h$^{-1}$ for the duration of the infusion in babies aged 3–12 months.

## Patients and methods

After obtaining Ethics Committee approval and informed consent from parents, we studied babies, aged 3–12 months, ASA I or II, undergoing major abdominal operations. We excluded babies born before 35 weeks' gestation.

General anaesthesia was induced using a volatile agent or propofol, and neuromuscular block was produced with atracurium or vecuronium. After intubation of the trachea the lungs were ventilated to a normal end-tidal carbon dioxide concentration with oxygen, nitrous oxide and a volatile agent. We then inserted a 23-gauge lumbar extradural catheter using a 19-gauge Tuohy needle (Portex Minipack System) and injected bupivacaine 1.25 mg kg$^{-1}$ (0.25% or 0.5%). Another two doses of 0.6 mg kg$^{-1}$ were given if indicated by changes in heart rate or arterial pressure, up to a maximum total dose during surgery of 2.5 mg kg$^{-1}$. Continuous infusion of 0.25% bupivacaine 0.375 mg kg$^{-1}$ h$^{-1}$ (equivalent to 0.15 ml kg$^{-1}$ h$^{-1}$) was then started for postoperative pain relief. No other analgesics were given during anaesthesia.

A second cannula was inserted into a peripheral vein during anaesthesia for later collection of blood samples and flushed with heparinized saline 10 u. ml$^{-1}$.

After surgery the babies were monitored with an apnoea alarm and pulse oximeter. Assessments by nursing staff of pain and sedation using four-point scoring systems and measurements of heart rate and ventilatory frequency were recorded every hour. Pain was assessed as nil, mild, moderate or severe. Sedation was assessed as awake and alert, occasionally drowsy but easy to arouse, drowsy most of the time but easy to arouse, or somnolent and difficult to arouse.

Approximately 2 ml of blood were obtained from the venous sampling cannula at 4, 8, 16, 24, 32 and 40 h after starting the continuous extradural infusion as long as the extradural infusion was running and the sampling cannula remained patent. Plasma was

removed by centrifugation, frozen immediately and stored at −20 °C. Total bupivacaine was assayed using a modification of a high pressure liquid chromatography (HPLC) method described for measurement of lignocaine and its metabolites.[2] The sensitivity of the assay was dependent on the volume of plasma and was approximately 0.1 μg ml$^{-1}$ for 100 μl and 0.02 μg ml$^{-1}$ for 500 μl. The coefficient of variation was 5%.

## Results

We studied eight babies. Mean age was 33 weeks (range 18–48 weeks) and mean weight 7.8 (5.6–9.3) kg (table 1). The mean initial dose of bupivacaine given was 1.2 (range 1.1–1.3) mg kg$^{-1}$. One baby was given two additional boluses of 0.5 mg kg$^{-1}$ during surgery (table 1). Extradural bupivacaine was infused at a mean rate of 0.38 (0.36–0.39) mg kg$^{-1}$ h$^{-1}$ for a mean of 31 (4–44) h.

One catheter was removed at 4 h from a baby undergoing laparotomy for closure of a colostomy. The extradural infusion had seemed adequate during surgery but after operation the baby was intermittently distressed. This was attributed to colic and was treated with an infusion of morphine. The other seven babies had renal or ureteric surgery. Their hourly pain scores were nearly all assessed as "no pain" and no score was higher than "mild pain". All babies were either "awake and alert" or "drowsy but easy to arouse" for the duration of the infusion, except for one who was difficult to arouse at the first assessment after returning to the ward. There was no clinical evidence of central nervous system toxicity in any baby.

The results for total bupivacaine plasma concentrations sampled from a peripheral vein are shown in table 2 and figure 1. Most concentrations were less than 2 μg ml$^{-1}$ but one baby had a concentration of 2.02 μg ml$^{-1}$ at 32 h. The same baby showed clear evidence of accumulation of bupivacaine throughout the extradural infusion.

We attempted to separate the free fraction of bupivacaine with a micro-partition system (Amicon) and measure its plasma concentration using HPLC. In most samples the volume of plasma obtained was insufficient for the separation method or the concentration of the free drug was below the sensitivity of the assay for the volumes of plasma available (approximately 0.1 μg ml$^{-1}$ for 100 μl).

## Discussion

Extradural analgesia for postoperative pain control has become a more common technique in paediatric anaesthesia since the introduction of equipment specifically designed for use in babies and children.[3–6] Plasma concentrations of local anaesthetics during continuous extradural infusion have been measured in few children,[1 7 8] or babies.[8 9] Babies less than 6 months of age have an even greater potential for local anaesthetic toxicity than older children and adults because the free fraction of drug is increased.[10] The increased free fraction probably results from lower concentrations of binding proteins, principally $\alpha_1$-acid glycoprotein and albumin. The free fraction decreases inversely with age as the plasma concentration of $\alpha_1$-acid glycoprotein increases.

Berde reported from data collected from the members of the Society for Pediatric Anesthesia that seizures can occur in children at plasma concentrations of bupivacaine as low as 2 $\mu$g ml$^{-1}$.[1] Our study showed that some babies accumulate bupivacaine during continuous extradural infusion and can reach plasma concentrations in the range associated with local anaesthetic toxicity in children, despite infusion rates less than the maximum recommended by Berde.[1] This supports the findings of Wolf and colleagues[8] who showed that continuous extradural infusion of bupivacaine in the accepted dose can produce plasma concentrations within the toxic range in children, and Larsson, Olsson and Lönnqvist,[9] who found that babies accumulate bupivacaine during continuous infusions.

Wolf and colleagues measured plasma concentrations of bupivacaine associated with continuous lumbar or thoracic extradural infusions in 20 children aged 2 months to 4 yr.[8] After operation bupivacaine was infused at 0.25–0.375 mg kg$^{-1}$ h$^{-1}$ and additional boluses were given, with a maximum dose in any 4 h of 1.6 mg kg$^{-1}$. Two children, weighing 10 and 8.3 kg, had concentrations of 2.5 and 3.7 $\mu$g ml$^{-1}$, respectively, at 24 h. No toxic side effects were reported.

Larsson, Olsson and Lönnqvist[9] measured plasma concentrations of bupivacaine at 6 and 12 h in seven babies aged 0–7 months given a continuous extradural infusion.[9] They injected an initial dose of bupivacaine 1.5–1.9 mg kg$^{-1}$ with adrenaline and then infused bupivacaine 0.5–0.83 mg kg$^{-1}$ h$^{-1}$ without adrenaline. These doses are greater than the maximum recommended.[1] Larsson, Olsson and Lönnqvist[9] found a marked increase in plasma concentrations between 6 and 12 h, demonstrating accumulation of bupivacaine. The mean concentration at 6 h was 1.59 $\mu$g ml$^{-1}$ (range 1.2–2.1 $\mu$g ml$^{-1}$) compared with 2.06 (1.53–2.98) $\mu$g ml$^{-1}$ at 12 h. Two babies had central nervous system side effects, probably related to bupivacaine toxicity.

In conclusion, we have shown that babies can accumulate bupivacaine and achieve plasma concentrations above the threshold for toxic side effects, despite infusion rates below the currently accepted maximum. Although we can make no comment on the plasma concentration of unbound bupivacaine in our patients, babies have been shown to have a higher free fraction, at least to the age of 6 months, and a greater potential for toxic side effects. The size of our sample was small but we believe an extradural infusion rate of 0.375 mg kg$^{-1}$ h$^{-1}$ is probably an absolute maximum for babies younger than 12 months.

# Analgesia after day-case knee arthroscopy: double-blind study of intra-articular tenoxicam, intra-articular bupivacaine and placebo

T. M. COOK, J. P. TUCKEY AND J. P. NOLAN

---

## Summary

Arthroscopy of the knee is performed regularly on a day-case basis. Intra-articular bupivacaine produces transient analgesia and reports of analgesia using intra-articular morphine have produced conflicting results. Non-steroidal anti-inflammatory drugs given systemically can provide effective analgesia for this procedure. In this study we attempted to determine if intra-articular tenoxicam provided useful analgesia after day-case arthroscopy. Sixty three ASA I–II patients were allocated randomly to one of three groups to receive 40 ml of a solution containing 0.9% saline (group Pla), 0.25% bupivacaine (group Bup) or tenoxicam 20 mg (group Ten). The injection was made into the knee joint at the end of surgery, 10 min before tourniquet deflation. Verbal rating and visual analogue pain scores (at rest and on knee flexion), use of analgesia, mobilization and disturbance by pain at home were recorded for the next 48 h. There were no differences between pain scores in any of the three groups when tested at rest or on movement. Less analgesia was used in the first 24 h by patients in the tenoxicam group but the difference in time to first analgesia was not statistically significant. Side effects and disturbance by pain were similar in all groups. The use of intra-articular tenoxicam 20 mg at the end of arthroscopy reduced oral analgesic requirements during the first day after operation but did not alter patients' perception of pain. (*Br. J. Anaesth.* 1997; **78**: 163–168)

---

Arthroscopy of the knee is associated with postoperative pain that may require systemic analgesia and can delay hospital discharge. It is common to undertake the procedure as a day case. Efforts have been made to determine the best method of pain relief, to maximize analgesia and minimize side effects. Analgesic approaches include systemic opioids or systemic non-steroidal anti-inflammatory drugs (NSAID).[1] The use of locally administered analgesia is appealing and intra-articular local anaesthetics[2 3] and more recently intra-articular opioids[4] have been reported to be effective.

In contrast with opioids, NSAID have principal effects peripherally and therefore local application to the site of injury should produce analgesia while minimizing systemic side effects.[5] We set out to determine if there is a role for intra-articular tenoxicam (Mobiflex) in the prevention of pain after knee arthroscopy.

## Patients and methods

Before starting the study the local Ethics Committee gave approval and the Medicines Control Agency provided an exemption to the product licence for tenoxicam. We studied 63 patients undergoing elective knee arthroscopy. All patients gave informed, written consent and were advised that the intra-articular use of the trial drugs was a non-licensed method of administration.

Patients receiving NSAID in the previous 7 days, who were allergic to NSAID or local anaesthetics, who had contraindications to NSAID or local anaesthetics, those who were or might be pregnant, those aged less than 16 yr or more than 75 yr and those known to have osteoarthritis of the knee were excluded. We also planned to exclude those patients found to have osteoarthritis at the time of surgery, although none was found.

Instruction was given on using a 100-mm visual analogue scale (VAS) with 0 mm labelled "no pain" and 100 mm "worst pain imaginable". Instruction was also given on completing a pain verbal rating scale (VRS): ratings were "no pain", "mild pain", "moderate pain" and "severe pain". Preoperative pain scores at rest and on movement were recorded.

No premedication was given. A standardized general anaesthetic was administered. A sleep dose of propofol and fentanyl 1 $\mu g\ kg^{-1}$ was followed by maintenance with isoflurane and 66% nitrous oxide in oxygen. Patients breathed spontaneously via a laryngeal mask airway and a circle breathing system. Monitoring included inspired oxygen, electrocardiograph, non-invasive arterial pressure, pulse oximetry and capnography.

Patients were allocated randomly (with sealed

Correspondence to T. M C

envelopes) to one of three groups. Group Bup received 0.25% bupivacaine 40 ml into the knee joint; group Ten received a 40-ml injection of 0.9% saline containing tenoxicam 20 mg; and group Pla received a placebo injection of 40 ml of 0.9% saline. These injections were administered into the knee joint, by the surgeon, 10 min before the limb tourniquet was deflated.

VAS and VRS scores were recorded 30, 60, 120 and 180 min after tourniquet deflation and on another five specified occasions over the first 48 h after surgery. All VAS and VRS scores were recorded "at rest" and "on movement" (knee flexion). Patients recorded their analgesic use over this time.

Additional analgesia was prescribed as co-proxamol (dextropropoxyphene hydrochloride 32.5 mg and paracetamol 325 mg) as required, up to eight tablets a day. A supply of co-proxamol was given to the patient to take home and patients were requested not to consume any other analgesics. Morphine 0.15 mg $kg^{-1}$ and co-proxamol were available on request while in hospital.

Age, weight, sex, preoperative pain scores, tourniquet times, surgical grade and surgical procedure were analysed (by one-way ANOVA and chi-square where appropriate) to exclude important differences between groups. Pain scores and analgesic requirements during the first 48 h were compared between groups using repeated measures ANOVA. The time to first analgesic use was studied by Kaplan–Meier survival analysis. Results were considered statistically significant when $P<0.05$. The statistical packages used were MS Excel (version 5.0) and SPSS for Windows (release 6.1) both running in MS Windows (release 3.1).

Previous studies suggested an SD of up to 20 mm for VAS scores after knee arthroscopy in patients receiving intra-articular analgesia.[6] With 20 patients in each group the study was designed to have 80% power to detect an 18-mm difference in VAS score at a 5% level of significance. We considered that differences of less than 18 mm would not be clinically significant.

## Results

Patient characteristics were similar in all groups with the exception that patients in group Bup were younger than those in the other groups. Indications

for surgery, distribution of diagnostic and interventional arthroscopy, duration of surgery and seniority of the surgeons did not differ significantly between groups (table 1). There were no significant differences in preoperative pain scores between groups. All patients completed the study. All questionnaires were returned but in some cases not all pain scores were completed.

There was no significant difference between groups in either VAS or VRS scores at any time, either at rest or during movement (figs 1–4).

The same number of patients (3) in each group received morphine. Time to first analgesia was longest in group Ten but the differences between groups was not significant and this was confirmed by survival analysis (fig. 5). All patients in group Pla requested analgesia within 6 h after surgery and in group Bup within 7 h. Four patients in group Ten required no analgesia for more than 8 h.

The number of co-proxamol tablets consumed in the first 24 h was significantly less in group Ten than in the other groups ($P$<0.05). The number of tablets taken in the first 48 h was less in group Ten than in the two other groups but this was not statistically significant (table 2). At home five patients took all the analgesia available to them in the first 48 h (16 tablets) while 10 patients took none.

There were no differences in the number of patients disturbed by pain on the first or second night after operation, or in reported adverse effects (table 3). All groups were similar in the time taken to mobilize. Mobilization was supervised by a physiotherapist who saw patients at least 2 h after operation. Most patients were mobile on the first attempt and 57 of the 60 patients were discharged during the same half-day. One patient from each group was admitted overnight (table 3).

## Discussion

Various factors have been implicated in pain after arthroscopy and the effectiveness of intra-articular analgesia. These include preoperative pain scores,[7] duration[7] and type of surgery,[8] seniority of surgeon,[7] use of general or regional analgesia,[3,9] volume injected,[3,10] addition of adrenaline[3] and timing of intra-articular injection relative to tourniquet deflation.[10] These findings are inconsistent and more importantly details have not been recorded or are poorly matched between studies. Not all studies were performed as day-cases,[11] premedication and peroperative opioid analgesia varied widely and in some studies suxamethonium was used.[3,9,11] Pain assessment varied, with few studies assessing pain on movement, and techniques of statistical analysis of pain scores differed. This makes the large number of studies difficult to compare. In the design of this study we attempted to use best practice in performance and analysis.

We included a placebo group in this study as the efficacy of intra-articular bupivacaine is not proved; we gave modest doses of fentanyl in the peroperative period for ethical reasons. Pain scores were assessed at rest and on movement and were comparable with those reported in most similar studies.

The availability of analgesia on demand may lead to a converging of pain scores, as differences in pain are translated into differences in behaviour and analgesic consumption. In this study differences between groups in measures of pain (VAS and VRS at rest, on movement and disturbance by pain at night) and behaviour (mobilization) were not statistically significant. The only statistically significant difference between groups was for analgesic use. Patients in group Ten used significantly less oral analgesia in the first 24 h than those in the two other groups. Time to first analgesia was twice as long in group Ten than in the other groups; this was not significant.

Some studies have found only small differences between analgesic requirements in intervention and placebo groups. In one study with no peroperative analgesia, 63% of patients in a placebo group required no analgesia in hospital and 29% used no analgesia at home.[12] The fact that some patients require negligible analgesia has led some to conclude that pain after arthroscopy is a poor model for testing efficacy of analgesics.[13] In this study 85% of our patients required analgesia at home and 25% were disturbed by pain on both of the first two nights after operation, while 15% took no analgesia at home. These findings do not suggest that pain after arthroscopy is insignificant but rather that it is variable.

Studies of intra-articular analgesia have revealed inconsistent findings, with local anaesthetics, particularly bupivacaine, found to be either ineffective[7] or effective only for short periods.[14] Intra-articular morphine has also been found to be ineffective,[3 6 10] to cause pain after injection[4] or to have a delayed onset of effect.[11 14] The combination of local anaesthetic and morphine has been found to provide rapid onset and prolonged analgesia[14] but also to be no more effective than morphine alone[10] or bupivacaine alone.[6]

NSAID are effective when given parenterally after arthroscopy[1] and may improve recovery.[15] The main site of action is peripheral, reducing nociception,[16] with fewer spinal effects.[5] NSAID may also reduce pain by modifying the local inflammatory process. As the pain of arthroscopy arises in the joint, it is logical to use a peripherally acting drug at the site of injury. One can postulate that using the drug locally may produce greater efficacy and reduced side effects. The difference in analgesia provided by matched doses of i.v. or intra-articular tenoxicam has not been determined and as this study had no i.v. group it did not test this hypothesis.

This study is the first blinded controlled examination of the use of an intra-articular NSAID for post-arthroscopy analgesia. The use of intra-articular ketorolac has been reported in three studies which claimed an analgesic effect equivalent to that of intra-articular local anaesthetic[17 18] and morphine.[19] These studies had no placebo group, used large doses (six times the current recommended parenteral dose) and in two studies pain scores were evaluated for only 2 h after operation. Diclofenac has also been used by the intra-articular route in an uncontrolled series of patients.[20] Good analgesia was reported but there have been reports of the injection causing both pain[19] and inflammation (personal communication, Ciba Pharmaceuticals).

Tenoxicam is an NSAID of the oxicam class with a prolonged elimination half-life.[21] It has a favourable side effect profile as it causes less gastrointestinal irritation than diclofenac SR, aspirin or indomethacin.[21] It has been used parenterally for knee arthroscopy[22] when it reduced pain in the first hour after operation. As the drug is water soluble and does not require a solubilizing agent, it is particularly suitable for intra-articular injection.

Several NSAID have effects on animal and human cartilage (reduced chondrocyte biosynthesis and cartilage destruction) *in vitro* and *in vivo* that can be deleterious,[23] particularly to patients with osteoarthritis. These effects vary between different NSAID.[24] In contrast with other NSAID, tenoxicam may not suppress chondro-formative processes in human osteoarthritic cartilage (*in vitro*)[25] and may have beneficial effects.[26] Further, tenoxicam tends to be concentrated in the synovium rather than the cartilage.[27] While there may be some question as to whether or not all NSAID are safe for intra-articular injection we believe tenoxicam is safe. Despite this, for safety reasons we excluded patients with osteoarthritis.

The prospect of using carefully selected NSAID intra-articularly raises the possibility of providing intra-articular "balanced analgesia". One study compared intra-articular ketorolac with intra-articular morphine and the combination of both.[18] Arthroscopies were performed under bupivacaine local anaesthesia with sedation. The conclusions were that each drug provided equivalent analgesia with no benefit from combining the two; there was no placebo group. It is not known if the anti-inflammatory effect of the NSAID interferes with peripheral opioid analgesia, which requires tissue inflammation for expression of peripheral opioid receptors.[3]

## Acknowledgements

We are grateful for advice on various parts of the study from Dr C. Stannard, Royal United Hospital, Bath and Dr A. Calin, Royal National Hospital for Rheumatic Diseases, Bath. We are grateful for statistical advice from Dr A. Black, Bristol Royal Infirmary, Bristol. Roche Pharmaceuticals provided tenoxicam for injection.

# Brain tissue oxygenation in patients with cerebral occlusive disease and arteriovenous malformations

W. E. HOFFMAN, F. T. CHARBEL, G. EDELMAN AND J. I. AUSMAN

## Summary

It is not clear if ventilation with oxygen increases brain tissue oxygen pressure ($P_{O_2}$) during ischaemia. We have measured brain tissue $P_{O_2}$, carbon dioxide pressure ($P_{CO_2}$) and pH during baseline anaesthesia and oxygen ventilation in non-ischaemic control patients ($n$=9), patients with cerebral occlusive disease ($n$=11) and patients with arteriovenous malformations (AVM, $n$=12). The same anaesthetic treatment was given to all groups and anaesthesia was constant during the study. Arterial pressure, brain temperature and arterial blood-gas tensions were similar between groups. Under baseline conditions, brain tissue $P_{O_2}$ was mean 4.2 (SD 1.4) kPa in the controls and was 70% lower in patients with ischaemia and AVM. Patients with occlusive disease also had elevated tissue $P_{CO_2}$ and acidosis. During oxygen ventilation, $P_{O_2}$ increased to 7.5 (2.9) kPa in controls and this was 50% greater than the increase in the ischaemia and AVM patients. The results showed that baseline tissue oxygenation and increases in $P_{O_2}$ during hyperoxia were attenuated in patients with ischaemia or AVM. (*Br. J. Anaesth.* 1997; **78**: 169–171)

**Key words**
Brain, ischaemia. Brain, carbon dioxide. Complications, arteriovenous malformation. Carbon dioxide, partial pressure.

Under normal conditions, brain tissue $P_{O_2}$ is reported to be in the range 3.3–5.2 kPa in animals and patients.[1–3] Tissue oxygenation may be inhibited by cerebral occlusive disease or by arterial venous malformations (AVM), which attenuate cerebral perfusion pressure by producing a low resistance shunt for blood flow.[4–6] It has been reported that the upper limit of tissue oxygenation is controlled in normal brain tissue during oxygen ventilation, but that these regulating mechanisms are missing after head injury.[3] Little is known of tissue changes in $P_{O_2}$ during hyperoxia in tissue affected by occlusive disease or AVM. The purpose of this study was to evaluate the effect of oxygen ventilation in patients with cerebral occlusive disease and AVM compared with non-ischaemic controls.

## Patients and methods

The studies were approved by the University of Illinois Institutional Review Board for Clinical Research and informed consent was obtained. Patients in group 1 ($n$=9) served as controls for the study. None of these patients bled or had clinical signs of ischaemia before surgery. Neurosurgery was performed in these patients for clipping of cerebral aneurysms. Patients in group 2 ($n$=11) had evidence of cerebral ischaemia, as determined by neurological examination or the presence of transient ischaemic episodes. Decreased regional cerebral perfusion was confirmed in these patients by single photon emission computed tomography (SPECT) or cerebral angiography. Six of these patients were undergoing extracerebral to intracerebral vascular bypass, two patients cerebral aneurysm surgery with confirmed cerebral vasospasm and three patients had a cerebral embolism. Patients in group 3 ($n$=12) were undergoing neurosurgery for AVM resection. Nine of these patients had previous neuroradiological AVM embolization procedures performed before AVM resection.

All patients were anaesthetized with thiopentone 3–5 mg kg$^{-1}$ and fentanyl 10–15 μg kg$^{-1}$. Tracheal intubation was facilitated with vecuronium 0.1 mg kg$^{-1}$ and the lungs ventilated with 0.5–1.5% isoflurane and oxygen in room air (inspired oxygen fraction=0.4). Oesophageal temperature was measured and allowed to decrease to approximately 34°C. Arterial carbon dioxide tension ($Pa_{CO_2}$) was adjusted to 3.9–4.6 kPa. Monitoring included mean radial arterial pressure (MAP) measured by a Marquette Electronics Tramscope (Milwaukee, WI, USA); end-tidal isoflurane and $P_{CO_2}$ were measured with a Datex Ultima (Helsinki, Finland).

After craniotomy, a $P_{O_2}$, $P_{CO_2}$, pH and temperature sensor (Paratrend, Biomedical Sensors, Malvern, PA) was inserted into cortex tissue (diameter=0.5 mm). The sensor is a sterile, disposable device comprised of two modified optical fibres

for measurement of $P\text{CO}_2$ and pH, a miniaturized Clark electrode for $P\text{O}_2$ measurement and a thermocouple for measurement of temperature. The sensor was calibrated with three precision gases supplied with the monitor before insertion into the patient. The gases are: 1=2% carbon dioxide, 15% oxygen, balance nitrogen; 2=5% carbon dioxide, 15% oxygen, balance nitrogen; 3=10% carbon dioxide, 15% oxygen, balance nitrogen. The calibration range and 95% confidence limits for each sensor have been determined in *in vitro* testing: oxygen (range 0–15.7 kPa, 95% confidence limits +0.1 kPa); carbon dioxide (range 1.3–10.5 kPa, 95% confidence limits +0.4 kPa); pH (range 6.80–7.80, 95% confidence limits +0.03). The 0% to 90% response time for each sensor is: oxygen=70 s, carbon dioxide=143 s, pH=78 s.[7] All monitored variables were collected by computer using Labview (National Instruments, Austin, TX) every 10 s.

When the sensor was inserted, baseline tissue gas tensions, pH and temperature, MAP and blood-gas tensions were measured after a 30-min equilibration period. Inspired oxygen fraction was increased from 0.4 to 1.0 for 10 min and then returned to baseline levels. Samples for arterial blood-gas measurements were obtained under baseline conditions and during oxygen ventilation.

Data are reported as mean (SD). Differences in mean values between the three groups were analysed by analysis of variance with *post hoc* testing if a significant *F* value was found. Differences between baseline and oxygen administration were analysed using paired *t* tests. If data distribution failed the underlying assumptions for normality and equal variance, non-parametric analyses using Kruskal–Wallis or Wilcoxon tests were performed.

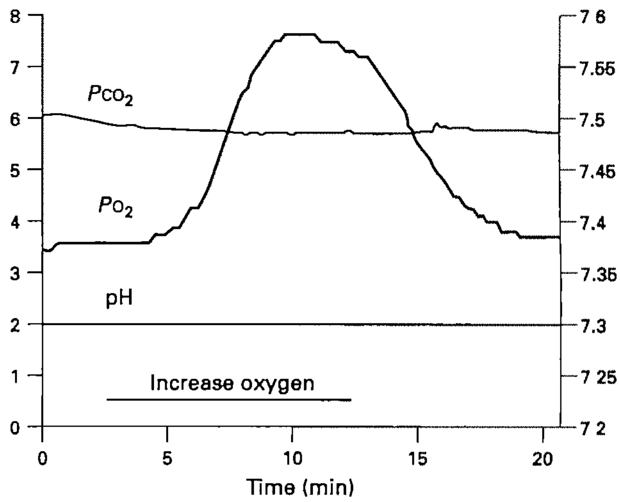

*Figure 1* Changes in $P\text{O}_2$, $P\text{CO}_2$ and pH during oxygen ventilation in a non-ischaemic patient. The scale for $P\text{O}_2$ and $P\text{CO}_2$ (kPa) is shown on the left and that for pH on the right. Oxygen ventilation produced an increase in $P\text{O}_2$ with no change in $P\text{CO}_2$ or pH.

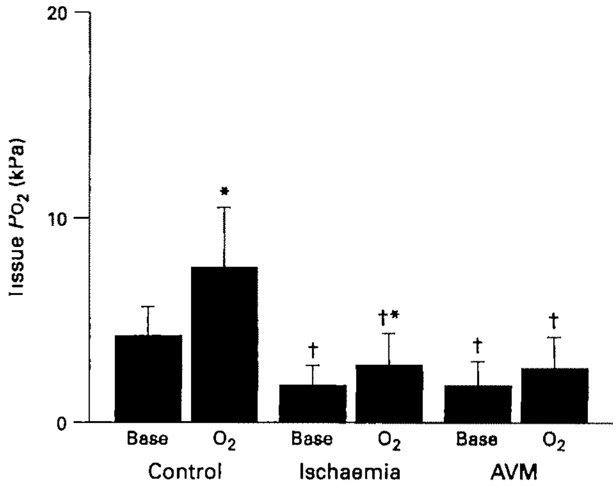

*Figure 2* Tissue $P\text{O}_2$ during baseline measurements (Base) and oxygen ventilation ($\text{O}_2$). Baseline $P\text{O}_2$ was greater in controls compared with those with cerebral occlusive disease and AVM. The increase in $P\text{O}_2$ during hypoxia was attenuated in cerebral occlusive disease and AVM compared with controls. *$P<0.05$ compared with baseline; †$P<0$ 05 compared with control.

## Results

Under baseline conditions, the physiological variables in table 1 were similar in control, ischaemic and AVM patients. With administration of 100% oxygen in the inspired gases, $Pa_{\text{O}_2}$ increased in all three groups to a similar degree. The response to oxygen ventilation in a normal patient is shown in figure 1. Tissue $P\text{O}_2$ increased in these patients during the increase in $Pa_{\text{O}_2}$ but there was no change in tissue $P\text{CO}_2$ or pH. Figure 2 show mean tissue $P\text{O}_2$ data for all patients. Under baseline conditions, tissue $P\text{O}_2$ decreased in ischaemic and AVM patients compared with controls, and the increase in $P\text{O}_2$ during oxygen administration was attenuated in ischaemic and AVM patients during hyperoxia. Tissue $P\text{CO}_2$ increased and pH decreased in ischaemic patients during the baseline period but neither variable changed during oxygen ventilation (table 1).

## Discussion

In non-ischaemic patients, we found a baseline tissue $P\mathrm{O_2}$ of 4.2 kPa. This is consistent with previous reports.[1–3, 8] During hyperoxia, tissue $P\mathrm{O_2}$ increased to 7.5 kPa in non-ischaemic patients. This agrees with the conclusions of Meixenberger and colleagues[3] that local mechanisms regulate the upper limit of tissue oxygenation. Tissue oxygenation decreased significantly in patients with cerebral occlusive disease and AVM under baseline conditions and during oxygen ventilation. This indicates that mechanisms which promote tissue oxygenation are attenuated in occlusive disease and AVM.

Previous studies have suggested that cerebral occlusive disease and AVM produce different types of ischaemia. Acute and chronic brain ischaemia during brain artery occlusion is associated with a decrease in $P\mathrm{O_2}$, an increase in $P\mathrm{CO_2}$ and acidosis.[1, 8–11] This is accompanied by loss of cerebrovascular reactivity to increases in $Pa_{\mathrm{CO_2}}$.[12] In contrast, with an AVM, cerebral tissue perfusion pressure and blood flow are decreased because of shunting of arterial blood flow away from normal tissue.[4–6, 13] Although AVM have been described as producing vascular paralysis and ischaemia,[14] studies have shown that carbon dioxide reactivity and pressure autoregulation are intact.[5, 6] In spite of the reported differences between these two types of ischaemia, we found that the tissue oxygenation response to oxygen ventilation was attenuated in both groups. This suggests that inadequate brain tissue oxygen delivery is a consistent problem in patients with cerebral occlusive disease and AVM.

In this study, patients with occlusive disease had significantly increased tissue $P\mathrm{CO_2}$ and decreased pH. This supports previous reports that carbon dioxide clearance is attenuated and metabolic acidosis may be present in these regions.[9, 11, 15, 16] In contrast, in tissue adjacent to an AVM, $P\mathrm{CO_2}$ and pH did not differ from control values, possibly because decreased tissue metabolism would lower carbon dioxide production and normalize pH in hypoxic tissue.[17] One concern is that the lack of change in brain tissue $P\mathrm{CO_2}$ and pH results from a lack of sensitivity of the sensors rather than absence of a tissue change. However, in previous studies we have shown that tissue $P\mathrm{CO_2}$ and pH change in patients during hypercapnic challenge.[9] This supports the fact that the lack of changes in tissue $P\mathrm{CO_2}$ and pH during increases in oxygen ventilation were accurate.

In summary, these results showed that brain tissue $P\mathrm{O_2}$ was lower in patients with cerebral occlusive disease and AVM compared with non-ischaemic patients. During oxygen ventilation, tissue $P\mathrm{O_2}$ increased (4.6 kPa) in control patients; this was significantly greater than the response in patients with occlusive disease and AVM. Simultaneous measurements of tissue $P\mathrm{CO_2}$ and pH indicated that the metabolic characteristics of occlusive disease and AVM were different but that inadequate tissue oxygenation was a consistent problem in both groups.

# Blood loss during first trimester termination of pregnancy: comparison of two anaesthetic techniques

J. E. HALL, W. S. NG AND S. SMITH

## Summary

We have compared the effects of two anaesthetic techniques on blood loss during suction termination of pregnancy. Forty-eight ASA grade I-II patients were allocated randomly to one of two groups: group 1 received propofol induction followed by a standard propofol infusion; group 2 received propofol induction followed by maintenance with 1% isoflurane. Both groups received bolus doses of either propofol (group 1) or isoflurane (group 2) if anaesthesia was too light. All patients were given fentanyl 1 $\mu$g kg$^{-1}$ on induction. The products of conception were evacuated into a closed suction bottle. The products were diluted with 500 ml of heparinized saline, filtered and left for 20 min. Estimation of blood loss was performed by atomic absorption spectrometry. Mean blood losses were 40.4 ml for the isoflurane group and 18.8 ml for the propofol group. This difference was statistically significant ($P$=0.0011), although actual volumes of blood loss were small and not clinically significant. (*Br. J. Anaesth.* 1997; **78**: 172–174)

**Key words**
Anaesthetics i.v., propofol. Anaesthetics volatile, isoflurane. Blood, loss. Surgery, gynaecological.

Suction termination of pregnancy is performed frequently, although the number of suction terminations has decreased recently as medical termination becomes more common. The operation is generally regarded as safe, although severe uterine haemorrhage may occur.

Volatile anaesthetic agents are often avoided during suction termination of pregnancy. Halothane, enflurane and isoflurane are known to depress the activity of the human myometrium leading to increased blood loss.[1] Because of the effect of volatile agents on the pregnant uterus, some anaesthetists prefer to use either intermittent bolus doses of propofol or propofol infusion, although on an empirical basis, as no study has investigated the effect of propofol on blood loss in the first trimester uterus.

## Patients and methods

The study was approved by the local research Ethics Committee. We studied 48 patients undergoing suction termination of pregnancy as a day-case procedure after obtaining written informed consent. All subjects were ASA I or II with a fetal gestational age of 9–12 weeks. Gestational age was determined clinically by dates and by bimanual examination. Patients were excluded before operation if the standard anaesthetic technique could not be followed. These factors included the patient having a known allergy to any of the anaesthetic agents and when body mass index was 50% greater than normal.

On the morning of operation, the patient's haemoglobin concentration was measured. All patients received a gemeprost 1 mg vaginal pessary at least 1.5 h before operation. Patients were excluded if any external blood loss was seen before operation. No premedication was given. Patients were allocated randomly to one of two groups to receive the following anaesthetics: group 1, after preoxygenation, patients received fentanyl 1 $\mu$g kg$^{-1}$ followed by an induction dose of propofol (2–3 mg kg$^{-1}$). A propofol infusion was started using a standard regimen of 12 mg kg$^{-1}$ h$^{-1}$ for 10 min, and then 9 mg kg$^{-1}$ h$^{-1}$ for 10 min. If anaesthesia was deemed to be light, it was supplemented with bolus doses of propofol (20 mg). Patients breathed 66% nitrous oxide in oxygen via a face mask; group 2, after preoxygenation, patients received fentanyl 1 $\mu$g kg$^{-1}$, followed by an induction dose of propofol (2–3 mg kg$^{-1}$). Anaesthesia was maintained with 1% isoflurane (measured concentration) and 66% nitrous oxide in oxygen via a face mask. If anaesthesia was deemed to be too light, isoflurane concentration was increased by 0.5%, and a further 0.5% if necessary, reverting to a concentration of 1% isoflurane when the patient had stabilized.

In the operating theatre, a screen separated the surgeon and anaesthetist. The time of the start of anaesthesia was noted, as was the time when dilatation of the cervix commenced. Oxytocin 10 u. was administered i.v. when the cervix was dilated. All terminations were performed by suction curettage

and uterine contents were aspirated into a closed system suction bottle. The surgeon assessed the quality of uterine contraction by bimanual examination and the operation was not considered complete until the surgeon was satisfied. Surgical and anaesthetic times were noted. Surgical time was the time between commencement of dilatation of the os and end of operation. Anaesthetic time was the time between giving the induction agent and discontinuation of nitrous oxide at the end of the procedure. Surgery and anaesthesia were performed by doctors graded senior SHO and above.

When the procedure was complete, the suction tubing was washed with 500 ml of heparinized normal saline. The contents of the suction bottle were then strained through a fine muslin mesh and left to drain for 20 min. The final sample of fluid was analysed for iron content by flame atomic absorption spectroscopy (FAAS).[2] Blood loss was calculated using the patient's haemoglobin concentration and iron content of the operative suction sample.

The results were analysed using a Minitab 2 sample Student's *t* test which does not rely on equality of variants. The results were considered significant when $P<0.05$.

## Results

We recruited 48 patients; four were withdrawn after consent had been gained: one because she received i.m. pethidine shortly before coming to the operating theatre, two patients had external blood loss after the gemeprost pessary was inserted and one was found to have an empty uterus on examination in theatre. Patient groups were similar in age, gestation of pregnancy, and surgical and anaesthetic times (table 1).

There was a highly significant difference between the two groups for blood loss (table 2).

## Discussion

Many studies have compared the effects of volatile and i.v. anaesthetic agents on uterine blood loss during termination of pregnancy. Halothane has been shown to cause increased blood loss during this procedure, although the results are not unequivocal. One large study[3] concluded that halothane led to increased blood loss, but the 87 patients studied were allocated to one of eight groups making each rather small. In addition, duration of anaesthesia was up to 35 min, which is prolonged by current standards. Increased blood loss was also shown with halothane in a comparison between halothane and alfentanil-supplemented anaesthesia.[4] Batt concluded that halothane was safe in spontaneous abortion,[5] in a large, although retrospective, 5-yr study. West and colleagues found that halothane did not differ from methohexitone and Althesin-supplemented anaesthesia.[6]

A study using enflurane[7] showed significantly increased blood loss compared with fentanyl-supplemented anaesthesia, but in this study high concentrations of enflurane (3%) were used and these would probably be avoided in current practice. There has been little work on newer agents, although Dolan, Eger and Margolis[8] in a small study concluded that isoflurane was in the same category as halothane in increasing blood loss during suction termination. This conclusion was based on a comparison with an earlier study.[3]

As Grant pointed out in an editorial,[9] this type of study suffers from the difficulties of measuring low blood loss. Commonly used techniques include measurement of volume collected by closed suction and colorimetric methods. It was felt that iron estimation by atomic absorption spectrometry might produce accurate results (see appendix). In fact, the measured blood loss in this study was similar to that in a recent study examining the use of oxytocin in suction termination of pregnancy, where colorimetric estimation was used.[10]

Our study attempted to mirror normal practice, using low concentrations of isoflurane, an i.v. induction agent and relatively brief surgical and anaesthetic times. In spite of these precautions there was still a statistically significant increase in blood loss with isoflurane. Admittedly, the anaesthetists and surgeons participating were not standardized, but all were experienced in the techniques required, the anaesthetic technique was accurately prescribed and all operations used suction curettage.

Total blood loss was low in both groups and the difference may not be clinically significant. The difference in blood loss could have more clinical relevance when general anaesthesia is given for planned terminations of a high gestational age or for evacuation of retained products of conception after incomplete spontaneous abortion. The latter operation is performed frequently between the eighth and 14th weeks of gestation and can be associated with considerable blood loss. This study suggests that the choice of anaesthetic technique could influence the degree of haemorrhage. In addition, if the differences in blood loss could be extrapolated from the first to the third trimester, there may be implications for haemorrhage during Caesarean section under general anaesthesia.

## Appendix

FAAS uses the principle that ground state atoms absorb electromagnetic radiation in a series of very narrow, well defined wavelengths, making the test very specific and sensitive. Iron is excited thermally and as it returns to its ground state it emits radiation of a characteristic wavelength The intensity of the radiation is directly proportional to the concentration of iron present. Blood loss was calculated using the patient's haemoglobin concentration and the iron content of the operative suction sample:

Haemoglobin molecular weight=64 458.

Haemoglobin contains four atoms of iron, that is 4×molecular weight of iron 55.85=223.7.

Therefore 1 g of haemoglobin contains (223 7/64 458) ×1000=3.47 mg Fe.

Haemoglobin lost by patient=
concentration of haemoglobin in sample×total volume of diluted sample.

$$\text{Blood loss by patient} = \frac{\text{Haemoglobin lost by patient}}{\text{Patient's haemoglobin concentration}}$$

# Use of heparinase modified thrombelastography in liver transplantation

S. A. HARDING, S. V. MALLETT, T. D. PEACHEY AND D. J. COX

## Summary

Severe coagulopathies can occur during liver transplantation, particularly after reperfusion of the grafted liver. Heparin release has been proposed as one of the factors contributing to this coagulopathy. We have analysed the thrombelastograph (TEG) traces of 55 patients after reperfusion using native and heparinase-treated samples. In almost all cases an abnormal native TEG was improved *in vitro* by heparinase, demonstrating the presence of heparin or a heparin-like substance. The heparinase-modified TEG allowed assessment of the underlying coagulation status, providing a rational guide to blood component replacement or treatment of fibrinolysis. (*Br. J. Anaesth.* 1997; **78**: 175–179)

**Key words**
Liver, transplantation. Measurement techniques, thrombelastography. Blood, anticoagulants, heparin.

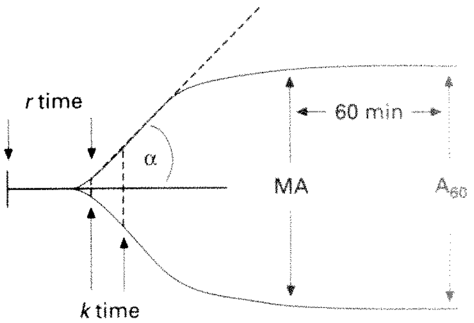

*Figure 1* Normal thrombelastographic trace. Normal range (plastic cup): $r$=21–30 mm, $k$=5–7 min, MA=45–54 mm and $\alpha$=30–40°.

Liver transplantation is frequently complicated by severe coagulopathies, particularly after reperfusion of the grafted liver. The cause of the marked deterioration in coagulation that accompanies reperfusion is incompletely understood but many potential factors have been implicated, including hyperfibrinolysis, DIC, platelet activation, trapping of platelets in the graft and a heparin-like effect.[1]

The thrombelastograph (TEG) has been shown to be a useful monitor of coagulation during liver transplantation and provides a rational approach to the use of blood component therapy or pharmacological intervention.[2] A normal TEG is shown in figure 1. Characteristic changes in the TEG trace occur after reperfusion of the grafted liver and have been described by several authors.[2–4] There is prolongation of the reaction time ($r$) and coagulation time ($r+k$), and a decrease in maximum amplitude (MA) and clot formation rate ($\alpha$). In our experience, the first TEG after reperfusion ($r$+10 min) frequently shows a straight line (no trace), demonstrating no clot formation during the 60 min that the sample is running. Several factors are thought to be responsible for this coagulopathy, including heparin release from the implanted liver graft. There have been several reports that document the presence of heparin-like activity immediately after reperfusion. The frequency of this heparin effect is reported to be between 25% and 95% of cases.[5 6]

Kang and colleagues have suggested that where there is demonstrated correction of the reaction time in blood treated with protamine sulphate *in vitro*, administration of protamine 50 mg can be used to antagonize the heparin effect *in vivo*.[1] Two cases have been reported where a coagulopathy developing 30 min after graft reperfusion was reversed clinically by protamine sulphate 50 mg, resulting in cessation of oozing from cut surfaces and normalization of the TEG.[7] Using protamine titration *in vitro*, Bakker and colleagues demonstrated a heparin effect in all of 15 recipients where heparin had been administered to the donor before removal of the liver graft and in one of five recipients whose donor had not been heparinized.[8] This suggests that heparin may bind to the endothelium during the donor procedure and subsequently be released into the circulation on reperfusion. It is standard practice in the UK to administer heparin 300 u. $kg^{-1}$ to all donors before organ harvesting. There may also be an additional component of endogenously derived heparin-like substance released by the donor liver from hepatic vascular endothelium damaged during ischaemia or reperfusion.

Heparinase is an enzyme obtained from *Flavobacterium heparinum* which specifically cleaves the polysaccharide portion of the anticoagulant

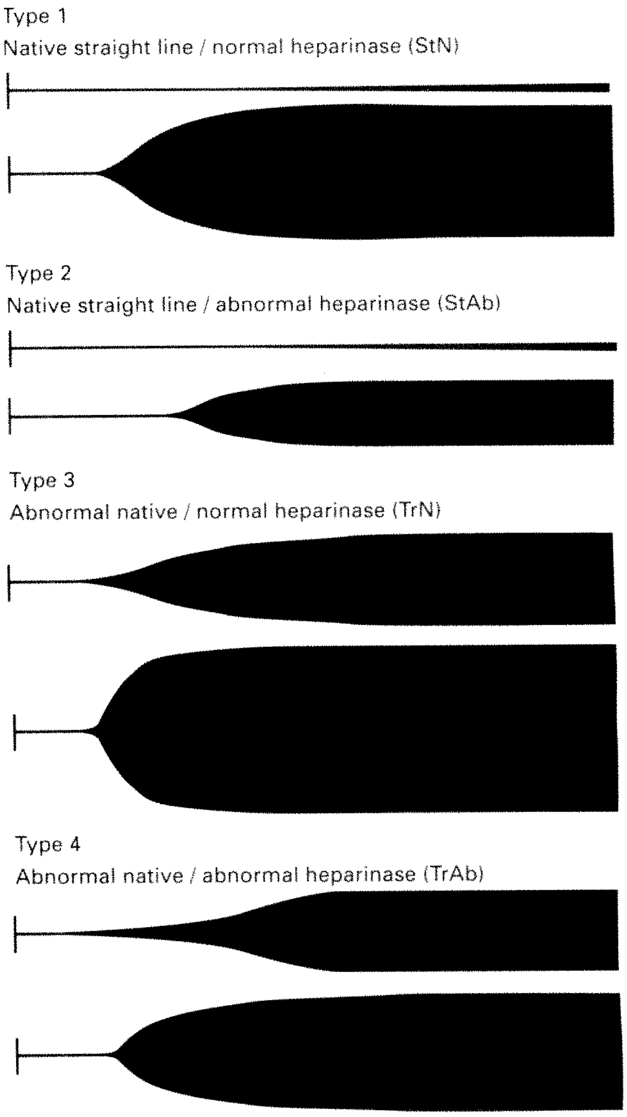
proteoglycans heparin and heparan sulphate. Dietrich, Silva and Michelacci demonstrated that heparinase catalyses an eliminase reaction directly within the antithrombin III binding site of heparin[9] making it a potent reagent for eliminating the anticoagulant effect of heparin. Heparinase has been shown to reverse the TEG effects of heparin and studies on normal volunteers have demonstrated that heparinase does not affect TEG variables of whole blood not containing heparin.[10] Protamine antagonizes the effects of heparin but may adversely affect coagulation if the dose of protamine is not matched to the quantity of heparin in the sample.[11]

We have shown previously that the hypocoagulable state demonstrated on the TEG is largely reversed by administration of heparinase *in vitro*.[12] Since 1994 we have been using heparinase-coated sample pots (Heparinase I, 2 u.; Haemoscope Corp) in the TEG run simultaneously with the native sample after reperfusion. Where an abnormal TEG is improved by heparinase, this demonstrates the presence of heparin or heparan sulphate. In this study, we analysed the TEG tracings of 55 patients undergoing liver transplantation.



Type 1
Native straight line / normal heparinase (StN)
Type 2
Native straight line / abnormal heparinase (StAb)
Type 3

Type 4
Abnormal native / abnormal heparinase (TrAb)

*Figure 2* Examples of thrombelastographic traces at reperfusion.

## Patients and methods

We examined the TEG tracings of 55 consecutive patients undergoing liver transplantation. Patients undergoing liver transplantation for fulminant hepatic failure were excluded. The diagnosis and Child's classification of the patients studied are given in table 1. Miscellaneous diagnoses were Wilson's disease (1), glycogen storage disease (1) and chronic active hepatitis (3). All blood samples for TEG analysis were obtained from a non-heparinized arterial cannula. Paired TEG traces were run simultaneously for all samples obtained after reperfusion. One sample had nothing added to it (native blood) and the other sample was treated with heparinase.

Patients were classified into four groups, according to the appearance of the TEG tracing at reperfusion + 10 min (R+10) (fig. 2). The native TEG sample was placed into one of two groups: a straight line (no trace) at 60 min or an interpretable trace within 60 min. The corresponding heparinase traces were also allocated to one of two groups: normal or abnormal, as defined by TEG variables. For the purposes of this study an abnormal trace was considered to be a coagulation time in excess of 60 mm of trace or a maximum amplitude of less than 35 mm, these being the values which we consider to require treatment with blood components at this stage of operation.

Total transfusion of blood and blood components were recorded for all three stages of the procedure. Red blood cells were transfused to maintain packed cell volume at 27–30%. Blood component therapy was administered on the basis of TEG criteria and the presence or absence of bleeding from surgical sites.

*Table 1* Diagnostic category and Child's classification

| | Child's A | Child's B | Child's C |
|---|---|---|---|
| Cirrhosis | 5 | 16 | 14 |
| PBC/PSC | 1 | 8 | 3 |
| Re-transplant | 0 | 1 | 2 |
| Miscellaneous | 1 | 2 | 2 |

Statistical analysis of blood transfusion requirements after reperfusion (unclamping of portal venous clamp and reperfusion of the liver to end of surgery) was carried out using the Kruskal–Wallis test with adjustment for ties. The Mann–Whitney *U* test was applied to individual groups.

Protamine 1 mg kg$^{-1}$ was given if a heparin effect was demonstrated on the TEG and there was clinical evidence of non-surgical bleeding caused by coagulopathy. Aprotinin (2 million kiu loading dose at the start of the procedure, followed by infusion of 500 000 kiu h$^{-1}$) was used according to our institutional criteria (patients with hepatic cirrhosis and those with markedly abnormal preoperative coagulation studies).

## Results

Analysis of the R + 10 TEG traces revealed only four of 55 traces which were unchanged by heparinase

*Table 2* TEG findings at reperfusion+10 min

| Native TEG | Heparinase TEG: normal trace | Heparinase TEG: abnormal trace |
|---|---|---|
| Straight line ($n$=39) | 18 | 21 |
| Interpretable trace ($n$=16) | 11 | 5 |

*Table 3* TEG groups: reperfusion+10 min. Stage III (after reperfusion) blood transfusion (mean (SEM) [range])

| TEG | $n$ | Received aprotinin | Received protamine | Blood transfusion (u.) |
|---|---|---|---|---|
| StN | 18 | 14 | 7 | 1.56 (0.63) [0-9] |
| StAb | 21 | 18 | 9 | 4.48 (1.26) [0-25] |
| TrN | 11 | 6 | 4 | 1.64 (0.43) [0-4] |
| TrAb | 5 | 4 | 2 | 1.40 (0.68) [0-3] |

(tables 2, 3); 39 of the native samples had a straight line TEG, of which all but one were improved by heparinase. The remaining patient had a straight line TEG which was unchanged by heparinase. This particular patient, who had received aprotinin, developed a severe coagulopathy after reperfusion which was not improved by infusion of FFP, cryoprecipitate and platelets, or administration of protamine. She died several hours after operation with intractable coagulopathy and circulatory collapse.

Sixteen patients had an interpretable trace at reperfusion; 13 of these were improved by heparinase. The three patients whose TEG was unchanged by heparinase at R+10 min developed prolongation of coagulation time in the native sample at R+30 min and demonstrated a heparin effect at that time. Where the native sample was a straight line, the heparinase sample revealed a normal TEG in 18 (46%) patients. Where the native sample was an interpretable trace, the heparinase trace was normal in 11 (69%) patients.

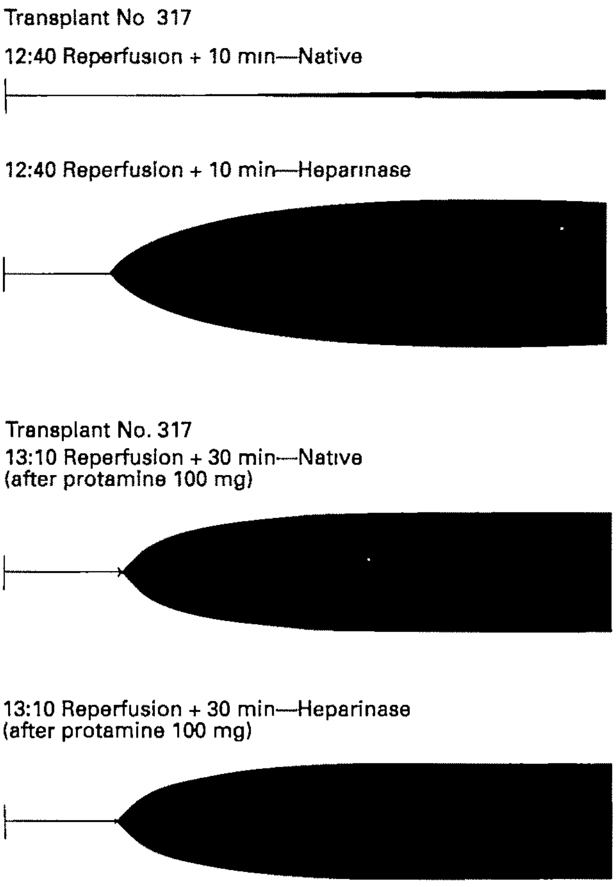

*Figure 3* Example of heparin effect reversed by protamine.

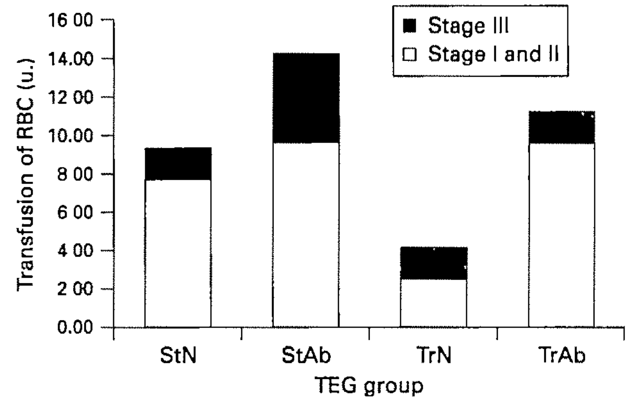

*Figure 4* Mean blood transfusion StN=Straight line native trace, normal underlying coagulation ($n$=18). Median transfusion stage III: 0 u of red blood cells (RBC) (range 0–9 u.), StAb=straight line native trace, abnormal underlying coagulation ($n$=21). Median transfusion stage III: 3 u. of RBC (range 0–25 u.); TrN=interpretable native trace, normal underlying coagulation ($n$=11). Median transfusion stage III: 1 u. of RBC (range 0–4 u.); TrAb=interpretable native trace, abnormal underlying coagulation. ($n$=5). Median transfusion stage III: 1 u. of RBC (range 0–3 u.) In stages I and II (dissection and anhepatic stage) blood loss (and therefore RBC transfusion) is generally related to surgical factors and the presence of portal hypertension, and is therefore presented separately to stage III (after reperfusion) blood loss which is more usually related to coagulopathy.

Protamine was administered in 26 cases. In cases where protamine was not administered, the heparin effect lasted 60–200 min. One patient who had received protamine developed recurrence of the heparin effect immediately after operation and received a second dose. In all cases where protamine was administered, correction of the TEG changes occurred (fig. 3).

Aprotinin was administered in 42 cases. In three of the 13 patients who did not receive aprotinin, the TEG after reperfusion was a straight line but the heparinase TEG revealed significant fibrinolysis which was treated with an i.v. bolus of tranexamic acid 500 mg. None of the patients who received aprotinin developed evidence of fibrinolysis on the TEG.

Mean blood transfusion for the four groups of patients is shown in figure 4. Statistical analysis of stage III (after reperfusion) transfusions revealed that patients who exhibited both a straight line native TEG and abnormal coagulation on the heparinase-modified trace (St Ab) had significantly higher transfusion requirements at this stage than any other group ($P$=0.01). There was no significant difference in stage III red blood cell (RBC) transfusion between patients who had an interpretable trace (irrespective of whether or not the heparinase-modified TEG was normal) and those patients who had a straight line TEG at reperfusion but had normal underlying coagulation ($P$=0.99).

Mean core temperature of the patients was 36.4 °C and at no time did any patient have a central temperature less than 35 °C.

## Discussion

The use of heparinase-modified TEG demonstrated the presence of heparin or a heparin-like substance after reperfusion of the grafted liver in all but one of the 55 patients studied. This "heparin effect" was variable both in magnitude and duration. The clinical significance of this heparin effect is uncertain as in many cases it is self-limiting and requires no specific treatment, however, in some patients it undoubtedly contributes to reperfusion bleeding. A "straight line" TEG in patients with good underlying coagulation rarely results in obvious bleeding at the wound site. There was no significant difference in stage III transfusion requirements between patients with good underlying coagulation irrespective of whether or not a marked heparin effect was demonstrated.

Our results indicate that patients who have an underlying coagulopathy are most sensitive to this effect. Transfusion requirements after reperfusion were significantly greater in patients who had both a "straight line" native TEG and abnormal underlying coagulation. In the absence of a heparin effect, poor coagulation treated according to conventional criteria did not result in significantly greater blood loss after reperfusion, but the numbers of patients in this particular group were insufficient to draw definitive conclusions.

It is possible that some liver transplant recipients may have a greatly increased sensitivity to heparin at reperfusion because of a combination of underlying coagulopathy and reduced heparin clearance. Clearance of heparin and heparan sulphate is known to be significantly prolonged in patients with liver disease[13] and it is possible that until the grafted liver achieves adequate function, that this is also the case in transplant recipients.

The origin of this heparin effect remains open to speculation but there is evidence for both exogenous and endogenous sources. All our donors had received heparin 300 u. kg$^{-1}$ according to standard UK practice. It is likely that this exogenously administered heparin contributes to this phenomenon,[14] even though the donor liver is flushed routinely with 4.5% albumin 500 ml before completion of the venous anastomoses. It is unclear if there is a significant component caused by endogenous heparan sulphate released from the damaged vascular endothelium of the ischaemic liver graft. Increased plasma concentrations of thrombomodulin are a marker of endothelial cell damage[15] and a sudden marked increase in concentrations have been demonstrated in liver transplant recipients within 5 min of reperfusion.[16] It has been shown that even in circumstances where the donor received no heparin, heparin-like activity, as demonstrated by protamine titration, may be present after reperfusion of the grafted liver.[8]

McKee and colleagues demonstrated increased concentrations of heparan sulphate in cirrhotic patients who bled from varices compared with matched controls who did not bleed but were unable to demonstrate a correlation with any other coagulation profile in the two groups. They concluded that the presence of this anticoagulant may have an important role in determining bleeding risk.[13] It is possible that heparan released into the systemic circulation from the ischaemic hepatic vascular endothelium at reperfusion similarly results in increased bleeding in patients who are excessively sensitive to its presence by virtue of poor underlying coagulation.

Where a marked heparin effect is demonstrated and the patient has clinical evidence of abnormal bleeding because of coagulopathy, administration of protamine sulphate 50–100 mg is of value. Correction of clotting factor and platelet deficiency should be undertaken simultaneously according to institutional procedures.

In conclusion, the presence of heparin or a heparin-like substance is demonstrable on the TEG in virtually all liver transplant recipients after reperfusion of the graft. This effect is so consistent, although variable in magnitude, that it most likely represents an inevitable accompaniment to reperfusion. Provided graft function is adequate, it is generally not a significant cause of bleeding after reperfusion and corrects spontaneously within 1–2 h. However, some patients may be excessively sensitive to these trace amounts of heparin or heparan and where a heparin effect is demonstrated and the patient has clinical evidence of abnormal bleeding caused by coagulopathy, protamine sulphate 1 mg kg$^{-1}$ should be administered. Neutralase (Heparinase 1) has recently been used successfully in human studies to reverse the effects of heparin[17] and may prove to be a preferable alternative to protamine as it lacks the potentially serious side effects of anaphylaxis and pulmonary vasoconstriction.

In our series, the native TEG trace after reperfusion was rendered uninterpretable in more than 50% of patients because of the presence of a marked heparin effect. Conventional criteria for administration of blood products based on the assessment of the native TEG at this stage could result in unnecessary or excessive treatment with blood component therapy. Use of the heparinase-modified TEG allows rapid assessment of the contribution of heparin to coagulopathy after reperfusion. In addition, the underlying coagulation profile is revealed, thereby facilitating the diagnosis of fibrinolysis, clotting factor or platelet deficiency and enabling appropriate therapy to be instituted.

The use of heparinase-modified TEG to monitor coagulation during liver transplantation provides useful additional information over native TEG alone and we would recommend its routine practice in this group of patients.

# Relationship between calculated blood concentration of propofol and electrophysiological variables during emergence from anaesthesia: comparison of bispectral index, spectral edge frequency, median frequency and auditory evoked potential index

M. Doi, R. J. Gajraj, H. Mantzaridis and G. N. C. Kenny

## Summary

We studied four electrophysiological variables (bispectral index (BIS), 95% spectral edge frequency (SEF), median frequency (MF) and auditory evoked potential index (AEP index)) in 10 patients during emergence from anaesthesia. We compared correlation of the signals with gradually decreasing calculated blood propofol concentrations, and evaluated the signal differences between preinduction and emergence from anaesthesia. Values of BIS, MF and SEF correlated with calculated blood concentrations of propofol during emergence from anaesthesia. The correlation was best with BIS, but was poor with MF and SEF at low calculated blood propofol concentrations. Although AEP index values did not correlate with calculated blood concentrations of propofol during emergence from anaesthesia, values after eye opening and before anaesthesia were well distinguished from those during emergence from anaesthesia. BIS correlated best with calculated blood concentrations of propofol. AEP index appeared to distinguish the awake from asleep state. (*Br. J. Anaesth.* 1997; **78**: 180–184)

**Key words**

Brain, evoked potentials. Monitoring, evoked potentials. Anaesthetics i.v., propofol. Anaesthesia, depth.

The major requirement of a monitor of anaesthetic depth is to distinguish consciousness from unconsciousness. Another desirable feature would be for the signal to provide an estimate of the effect of a given brain concentration of an anaesthetic agent to predict movement or awareness. Several processed EEG variables have been studied for use as a monitor of anaesthetic depth, including bispectral index,[1-3] median frequency[4,5] and 95% spectral edge frequency.[3,5,6] Although middle latency auditory evoked potentials (MLAEP) have been reported to correlate well with anaesthetic depth[7] and to be able to demonstrate potential awareness,[8,9] MLAEP are usually obtained intermittently and the waveforms are difficult to use in the clinical situation. More recently, the auditory evoked potential index (formerly known as the level of arousal score), derived from auditory evoked potentials, has been proposed as a single numerical variable for monitoring depth of anaesthesia.[10-12] The auditory evoked potential index reflects the morphology of the auditory evoked potential curves and is calculated from the amplitude difference between successive segments of the curve. A moving time average of the auditory evoked potential index is obtained at 3-s intervals.

The purpose of this study was to compare the four variables, bispectral index, median frequency, 95% spectral edge frequency and auditory evoked potential index, recorded simultaneously during emergence from propofol anaesthesia. In this situation, propofol concentrations in the brain would change in parallel with those in blood. We studied the correlation of the four variables with calculated blood concentrations of propofol, as a substitute for brain concentrations. The ability of the four variables to distinguish consciousness from unconsciousness was also investigated.

## Patients and methods

After obtaining approval from the Ethics Committee and informed consent, we studied 10 female patients undergoing minor surgery: five for diagnostic laparoscopy, four for ligation of varicose veins and one for hysteroscopy. Mean age was 31.2 (range 17–49) yr and mean weight 60.9 (47–72) kg.

All patients were unpremedicated and had been fasted for at least 6 h. A single dose of fentanyl 50–75 µg was given immediately before induction of anaesthesia. Anaesthesia was induced and maintained with target-controlled infusions of propofol[13] and a laryngeal mask was inserted. The target-controlled infusion system was operated by a three-compartment pharmacokinetic model "Diprifusor". Mean

values of minimum and maximum target blood concentrations of propofol during anaesthesia were 3.8 (range 2–5) and 9.6 (6–14) μg $ml^{-1}$, respectively. Anaesthesia was supplemented with 66% nitrous oxide in oxygen and ketorolac 10 mg i.v. Patients breathed spontaneously throughout the study. After discontinuation of propofol infusion and nitrous oxide inhalation, patients were prompted verbally to open their eyes. The observer was unaware of the values being measured. Consciousness was deemed to be present when patients opened their eyes to command.

### SURFACE EEG ANALYSES

The EEG was obtained from four disposable silver–silver chloride electrodes (Zipprep, Aspect Medical Systems, MA, USA) placed on both sides of the outer malar bone (At1 and At2), with Fpz as the reference and Fp1 as the ground. Impedance of the electrodes was confirmed to be less than 2000 Ω. Bispectral index, median frequency and 95% spectral edge frequency were measured using an EEG monitor (A-1000, BIS 3.0 algorithm, rev. 0.40 software, Aspect Medical Systems, MA, USA). Bispectral index, median frequency and 95% spectral edge frequency required at least 30 s to be fully updated. Data were stored automatically on a microcomputer (T1950CT, Toshiba, Japan) at 5-s intervals. The EEG before induction of anaesthesia was obtained when the patient's eyes were closed.

### AUDITORY EVOKED POTENTIALS ACQUISITION

Auditory evoked potentials (AEP) were obtained using a similar system to that described in our previous study[8] from three electrodes (Zipprep) placed at the right mastoid (+), and middle forehead (−), with Fp2 as the reference. The amplifier was custom-built with a 5 kV medical grade isolation. It had a common mode rejection ratio of 170 dB with balanced source impedance, input voltage noise of 0.3 μV (10 Hz–1 kHz rms) and current input noise of 4 pA (0.05 Hz–1 kHz rms). A third-order Butterworth analogue band-pass filter with a bandwidth of 1–220 Hz was used. The clicks were 70 dB above the normal hearing level and had a duration of 1 ms. They were presented at a rate of 6.9 Hz to both ears. The amplified EEG was sampled at a frequency of 1778 Hz by a 12-bit analogue-to-digital converter (PCM-DAS08, Computer Boards Inc., MA, USA) and was processed in real-time by the microcomputer. Auditory evoked potentials were produced by averaging 256 sweeps of 144 ms duration. The time required for a full update of the signal was 36.9 s, but a moving time averaging technique allowed a faster response time to any change in the signal. The auditory evoked potentials were obtained at 3-s intervals. The auditory evoked potential index is a mathematical derivative reflecting morphology of the AEP. The value was calculated as the sum of the square root of the absolute difference between every two successive 0.56-ms segment of the AEP waveform.[12]

Each variable was recorded simultaneously and mean values were obtained at intervals of 15 s. Mean values of the four variables were analysed using linear regression analysis against the calculated blood propofol concentration simulated by the "Diprifusor" pharmacokinetic model[13] during the emergence phase of anaesthesia, after discontinuation of propofol infusion and nitrous oxide inhalation until eye opening. The 95% prediction bands of the values were also obtained. Minitab for Windows was used for statistical analysis. Mean values obtained in the 15-s period just before induction of anaesthesia and those in the 15-s period just after eye opening to command were compared with the 95% prediction band. Values before induction and after eye opening were also compared with values just before eye opening using the Kruskal–Wallis and Tukey's tests. $P<0.05$ was considered statistically significant.

## Results

Mean duration of surgery and anaesthesia were 13.3 (range 5.5–30.2) min and 28.6 (18.6–46.1) min, respectively. Mean time interval from discontinuation of propofol infusion and nitrous oxide inhalation until eye opening was 8.6 (6.6–12.5) min. Mean calculated propofol concentration in blood at the time of eye opening was 1.9 (1.3–2.2) μg $ml^{-1}$.

Bispectral index values before eye opening correlated well with the calculated blood concentration of propofol (fig. 1). All bispectral index values before induction of anaesthesia and all values after eye opening were distributed in the 95% prediction band of the values before eye opening. Mean bispectral index values before and after eye opening did not differ from each other, but were significantly smaller than before induction of anaesthesia (fig. 5).

The 95% spectral edge frequency values before eye opening also correlated well with the calculated blood concentration of propofol (fig. 2). Although

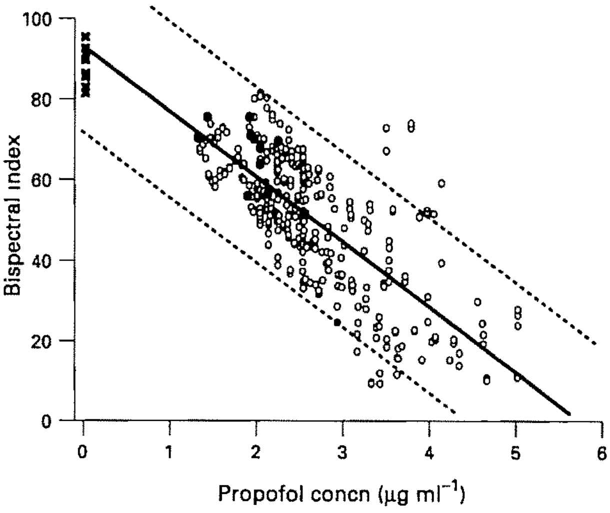

*Figure 1* Calculated propofol blood concentration *vs* bispectral index (○=before eye opening; ●=after eye opening; ×=before induction of anaesthesia). The linear regression line with 95% prediction band was analysed between calculated propofol concentration and values before eye opening. Bispectral index before eye opening was linearly related to propofol blood concentration (bispectral index=−12.8 (propofol)+93 6; $r=0.734$, $n=349$).

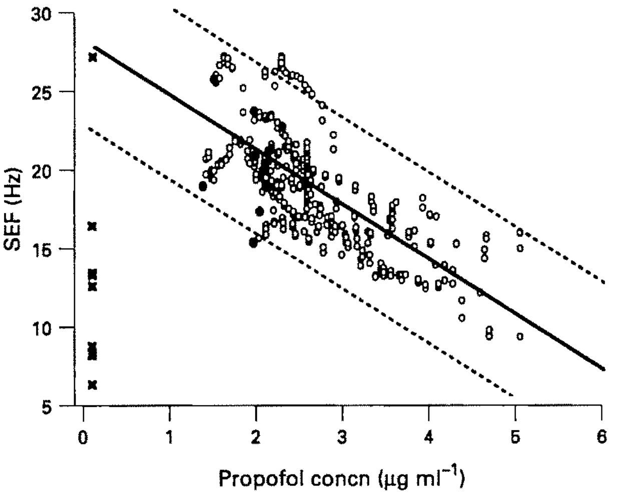

*Figure 2* Calculated propofol blood concentration *vs* 95% spectral edge frequency (SEF) (O=eye opening; ●=after eye opening; X=before induction of anaesthesia). The linear regression line with 95% prediction band was analysed between calculated propofol concentration and values before eye opening. The 95% SEF before eye opening was linearly related to propofol blood concentration (95% SEF=−3 44 (propofol)+27.9, $r$=0.686, $n$=349).

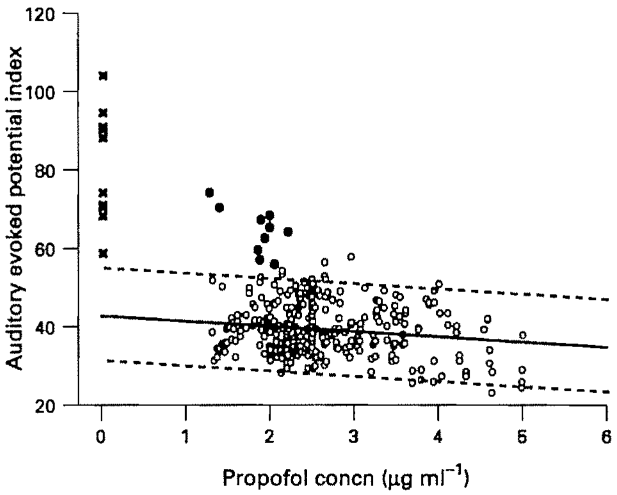

*Figure 4* Calculated propofol blood concentration *vs* auditory evoked potential index (O=before eye opening; ●=after eye opening; X=before induction of anaesthesia). The linear regression line with 95% prediction band was analysed between calculated propofol concentration and values before eye opening ($n$=349). The auditory evoked potential index before eye opening was not related to propofol blood concentration. The values after eye opening and before induction of anaesthesia were distributed above the prediction band and were well distinguished from those before eye opening.

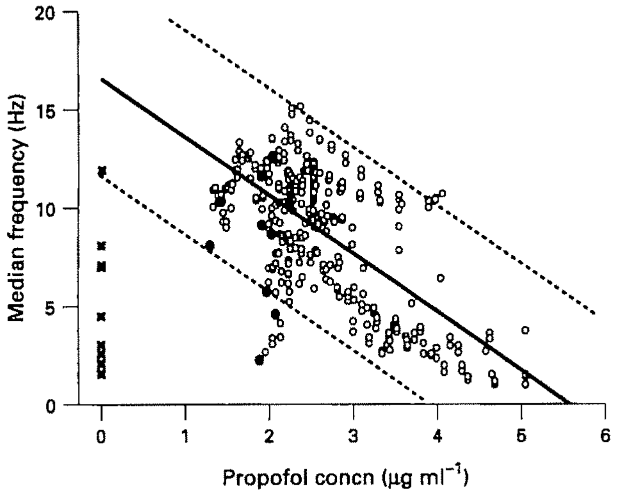

*Figure 3* Calculated propofol blood concentration *vs* median frequency (O=before eye opening; ●=after eye opening; X=before induction of anaesthesia). The linear regression line with 95% prediction band was analysed between calculated propofol concentration and values before eye opening. Median frequency before eye opening was linearly related to propofol blood concentration (median frequency=−2.98 (propofol)+16.5; $r$=0.647, $n$=349).

most of the values after eye opening were distributed within the 95% prediction band, those before induction of anaesthesia were spread widely below the band. The 95% spectral edge frequency values at a propofol blood concentration of zero had poor correlation with the regression line during anaesthesia. Mean 95% spectral edge frequency values just before and after eye opening were not different from each other, but significantly larger than before induction of anaesthesia (fig. 5).

Median frequency values before eye opening also correlated with blood concentrations of propofol (fig. 3). Values after eye opening were small and distributed below the regression line. Values before induction of anaesthesia were very small and spread mainly below 8 Hz, far below the prediction band. Median frequency values at a propofol blood concentration of zero showed poor correlation with the regression line during anaesthesia. There was no difference in mean median frequency values before induction of anaesthesia, before eye opening and after eye opening (fig. 5).

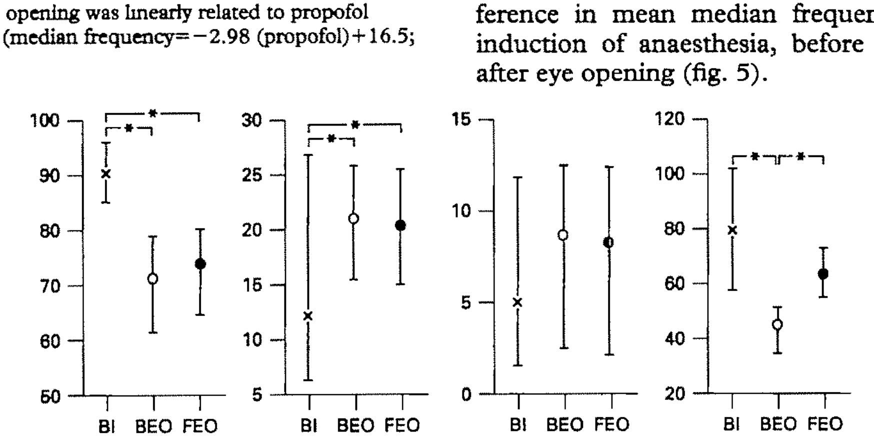

*Figure 5* Mean (range) values of the four variables at three periods: before induction of anaesthesia (BI, X), just before eye opening (BEO, O) and just after eye opening (FEO, ●) ($n$=10). *$P<0.05$ between two values.

Although auditory evoked potential indexes did not correlate with blood propofol concentrations before eye opening, they were distributed closely around 40, between blood propofol concentrations of 1 and 5 μg $ml^{-1}$, before recovery of consciousness. Auditory evoked potential indexes after eye opening and those before induction of anaesthesia were clearly distinguished from those before eye opening (fig. 4). There was no difference between values just before induction of anaesthesia and those recorded just after eye opening. Mean auditory evoked potential index before eye opening was significantly smaller than that after eye opening and also significantly smaller than that before induction of anaesthesia (fig. 5).

## Discussion

An appropriate performance measure is needed to evaluate and compare potential indicators of anaesthetic depth.[14] In this study, we examined four EEG variables using two methods: first, comparing values just before and after eye opening, and before induction of anaesthesia; second, investigating the correlation with calculated blood propofol concentrations. Eye opening is considered one of the "gold standard" indicators of anaesthetic depth during recovery. Blood propofol concentrations would be controversial as a indicator of anaesthetic depth because blood concentrations do not always reflect brain concentrations. This study was limited to the period during emergence from anaesthesia after discontinuation of propofol infusion. Although it was not a steady state, propofol concentrations in the brain would change in parallel with those in blood, which minimizes the discrepancy of propofol concentrations between blood and effector sites.

Chassard and colleagues reported that although propofol had little effect on brainstem auditory evoked potentials, it markedly suppressed the MLAEP, even at low concentrations. They could not identify Pa or Nb at propofol concentrations of 1.6–2.44 μg $ml^{-1}$.[15] Thornton and colleagues also reported that propofol profoundly affected the MLAEP[7] and speculated that the MLAEP reflected the hypnotic component of an anaesthetic agent. However, they did not study the transition from unconsciousness to consciousness. In this study we observed low auditory evoked potential indexes during sleep which increased suddenly just after eye opening. This suggested that the auditory evoked potential index reflected the level of consciousness rather than blood concentration of propofol. The auditory evoked potential index may therefore be a reliable monitor to detect awareness during anaesthesia.

Leslie and colleagues[3] reported that the bispectral index was monotonically related to blood concentrations of propofol; this finding is compatible with our study. This suggests that the bispectral index reflects the effect of given blood concentration of propofol. However, bispectral index values at the time of recovery of consciousness vary among studies. Howell and colleagues[16] reported that bispectral index values at the time of recovery of consciousness were 79.7 (SEM 3) during emergence from propofol anaesthesia and 82.1 (2) during emergence from propofol and alfentanil anaesthesia. Flaishon, Sebel and Sigl[17] reported that unconsciousness was not observed above a bispectral index of 70 and no consciousness was observed below a value of 65. We observed the transition from unconsciousness to consciousness at bispectral index values of 64–80. Kearse and colleagues[18] also reported that the bispectral index value that predicts 95% probability of unconsciousness was 52. The results of these studies suggest that a patient may recover consciousness at a bispectral index value of 50–85, but with an increasing probability at a higher value of the index. Our study revealed that bispectral index values before and after eye opening were not different. This suggested that the bispectral index could not detect the transition from unconsciousness to consciousness, where consciousness was defined as response to command.

Although 95% spectral edge frequency has been used widely to assess depth of anaesthesia, it showed large variability at low blood propofol concentrations. The variability was larger than that reported by Schwender and colleagues,[19] however our finding was comparable with that of Leslie and colleagues.[3] In our study and that of Leslie and colleagues, some subjects had low 95% spectral edge frequency values of less than 10 Hz. This might result from measurement when the eyes were closed. Median frequency also showed large variability, especially at low blood propofol concentrations. The large variability when awake may make assessment of anaesthetic depth difficult. This study demonstrated that the bispectral index was superior to 95% spectral edge frequency and median frequency in this respect.

These three variables, bispectral index, 95% spectral edge frequency and median frequency, demonstrated different characteristics from the auditory evoked potential index. The former three variables were derived from the same two-channel surface EEG signals. They are considered to reflect mainly cerebral cortex activity. Therefore, they correlated with blood propofol concentrations during emergence from anaesthesia. In contrast, the auditory evoked potential index was calculated from 144 ms of auditory evoked potentials. It reflects overall responses to auditory stimuli from the brainstem to the cerebral cortex. Although we have not identified the components of the waveforms, the overall responses demonstrated the transition from unconsciousness to consciousness very sharply, which mirrors the clinical state.

Blood concentrations of propofol were not measured but were calculated using a pharmacokinetic model.[20] However, in a previous study using a target control infusion system with the pharmacokinetic model,[21] discrepancies between calculated and actual blood concentrations were small after discontinuation of propofol infusion. The bias (mean prediction error) was −2%, and precision (mean of individual absolute prediction errors) was 15.1%.

This study was performed after the end of surgery. Therefore, the relationship between blood propofol concentration and the variables was not affected by the variable levels of surgical stimulation.[22]

Inhalation of nitrous oxide was discontinued at the same time as cessation of propofol infusion. Although the effects of nitrous oxide on auditory evoked potentials are weak,[23] a simultaneous decrease in nitrous oxide tension could influence the results. This study, therefore, could not determine the absolute relationship between propofol blood concentrations and the four variables; auditory evoked potential index or bispectral index required 36.9 s or 30 s, respectively, to be fully updated. Values measured 15 s after eye opening, therefore, included some components of values obtained before eye opening.

Within these limitations, we found different characteristics of the four variables for monitoring depth of anaesthesia. The variables processed from the surface EEG (bispectral index, 95% spectral edge frequency and median frequency) generally reflected blood concentrations of propofol. Of the three variables, bispectral index changed most linearly with propofol concentrations in blood. Therefore, bispectral index may provide the best prediction of recovery of consciousness during emergence from anaesthesia at the end of surgery.

Median frequency and 95% spectral edge frequency changed linearly when patients were unconscious, but lost the linearity during consciousness. Bispectral index was superior to median frequency and 95% spectral edge frequency. The auditory evoked potential index was different from the surface EEG derivatives and was the best variable to distinguish the transition from unconsciousness to consciousness.

LABORATORY INVESTIGATIONS

# Do local anaesthetics interact with dihydropyridine binding sites on neuronal L-type $Ca^{2+}$ channels?†

K. HIROTA, T. BROWNE, B. L. APPADU AND D. G. LAMBERT

## Summary

We have examined the interaction of procaine, prilocaine, lignocaine, bupivacaine, amylocaine and R(+) and S(−) ropivacaine with L-type voltage-sensitive $Ca^{2+}$ channels in rat cerebrocortical membranes. Membranes were prepared in Tris HCl 50 mmol litre$^{-1}$, pH 7.4, by homogenization and centrifugation. Binding assays were performed in 1-ml volumes of Tris HCl 50 mmol litre$^{-1}$, pH 7.4, for 90 min at room temperature using approximately 200 μg of protein. Non-specific binding was defined in the presence of nifedipine $10^{-5}$ mol litre$^{-1}$, and bound and free radioactivity were separated by vacuum filtration. The effects of local anaesthetics were determined by displacement of [$^3$H]PN200-110 (approximately 0.2 nmol litre$^{-1}$), a radiolabelled 1,4- dihydropyridine (DHP) L-channel antagonist. The concentration of displacer producing 50% displacement was corrected for the competing mass of [$^3$H]PN200-110 to yield the affinity constant, $K_{50}$. All local anaesthetics displaced [$^3$H]PN200-110 in a dose-dependent manner with a rank order potency of ($K_{50}$, mmol litre$^{-1}$) bupivacaine (0.48), amylocaine (0.74), lignocaine (1.09), prilocaine (2.06) and procaine (2.09). Ropivacaine enantiomers did not show stereoselective displacement, with $K_{50}$ values of 0.99 and 0.92 mmol litre$^{-1}$ for R(+) and S(−) ropivacaine, respectively. There was a significant correlation between p$K_{50}$ and p (octanol:buffer partition coefficient) ($r^2$=0.872, $P$=0.020), p$K_{50}$ and p (local anaesthetic potency) ($r^2$=0.816, $P$=0.036), p$K_{50}$ and p (relative conduction blocking potency) ($r^2$=0.843, $P$=0.028) and between p$K_{50}$ and p ($IC_{50}$ for inhibition of cardiac output) ($r^2$=0.897, $P$=0.015). These data suggest that DHP binding sites may be involved in both the mechanism of local anaesthesia and the cardiotoxicity of these agents. (*Br. J. Anaesth.* 1997; **78**: 185–188)

**Key words**
Anaesthetics local. Ions, ion channels. Ions, calcium. Model, rat.

It is well known that local anaesthetic agents inhibit voltage-sensitive $Na^+$ channels.[1–4] However, several studies[5–9] have suggested that clinically relevant concentrations of these agents also interact with voltage-sensitive $Ca^{2+}$ channels (VSCC) although the interaction may be weaker.[8] In an electrophysiological study, Sugiyama and Muteki[9] reported that the rank order of high voltage-activated (HVA) calcium current ($I_{Ca}$) inhibition was similar to their clinical rank order of potency. Moreover, Omote and colleagues[10] reported that the L-type VSCC blocker, verapamil, potentiated spinal anaesthesia induced by local anaesthetics. We have shown recently that a range of i.v. anaesthetic agents interact with 1,4-dihydropyridine (DHP) binding sites on L-type VSCC and suggested that this site may be a target for anaesthetic agents.[11]

In this study we have examined if a range of local anaesthetic agents (procaine, prilocaine, lignocaine, bupivacaine, amylocaine and R(+)/S(−)ropivacaine) interact with the DHP binding site in rat cerebrocortical membranes.

## Materials and methods

### TISSUE PREPARATION

Female Wistar rats (250–300 g) were stunned, decapitated and then the brain rapidly removed. The cerebral cortex was detached from its internal structures, placed in Tris HCl 50 mmol litre$^{-1}$, pH 7.4, at 4 °C and homogenized using a tissue tearer (setting 5, 5×30-s bursts). The homogenate was centrifuged at 18 000×$g$ for 10 min and the pellet resuspended in Tris HCl buffer. This procedure was repeated three times. The crude cell membrane preparation was frozen in aliquots at −40 °C.

### MEASUREMENT OF [$^3$H]PN200-110 BINDING

All binding assays[12] were performed in 1-ml volumes of Tris HCl buffer for 90 min at 20 °C using cerebrocortical membranes containing approximately 200 μg of protein. Non-specific binding was defined

†Presented in part at the Anaesthetic Research Society, Nottingham Meeting, March 28–29, 1996 (*British Journal of Anaesthesia*, 1996; 77: 290P)

in the presence of excess nifedipine ($10^{-5}$ mol litre$^{-1}$).[11] After incubation, each sample was filtered under vacuum through Whatman GF/B filters using a Brandel cell harvester to separate bound and free radioactivity. Filter retained (bound) radioactivity was extracted for at least 8 h in 4 ml of scintillation fluid before estimation using a β-scintillation counter. Estimated radioactivity was quench corrected with an average [$^3$H] counting efficiency of 60.4%. In order to determine if local anaesthetics interacted with DHP binding sites on L-type Ca$^{2+}$ channels, the DHP binding site was labelled with [$^3$H]PN200-110. Increasing concentrations of unlabelled displacer (local anaesthetics) were then added. Displacement of [$^3$H]PN200-110 binding by local anaesthetics indicates that they are interacting at the same site as the radiolabel. A fixed concentration of [$^3$H]PN200-110 (approximately 0.2 nmol litre$^{-1}$) was displaced by the following unlabelled agents ($n$=5–6 for each): bupivacaine $3\times10^{-5}$–$3\times10^{-3}$ mol litre$^{-1}$, lignocaine $10^{-4}$–$3\times10^{-2}$ mol litre$^{-1}$, prilocaine $10^{-4}$–$3\times10^{-2}$ mol litre$^{-1}$, procaine $10^{-4}$–$3\times10^{-2}$ mol litre$^{-1}$, amylocaine $3\times10^{-5}$–$10^{-2}$ mol litre$^{-1}$ and ropivacaine optical isomers, R(+) and S(−) ropivacaine $10^{-6}$–$3\times10^{-2}$ mol litre$^{-1}$. Local anaesthetic stock solutions were prepared in distilled water at least 50 times higher than the top concentration required. All were then diluted in Tris HCl buffer. The highest concentration of bupivacaine used was limited by agent solubility. With the exception of ropivacaine which was a gift from Astra (Sweden), all local anaesthetic agents were purchased from Sigma Chemical Co Ltd (Poole, Dorset, UK).

### DATA ANALYSIS

Specific binding was calculated as the difference between total and non-specific binding. Concentrations of displacer producing 50% displacement of specific binding were obtained by computer-assisted curve fitting (Graphpad-Prism) and corrected for the competing mass of [$^3$H]PN200-110 to yield the affinity constant ($k_{50}$ presented as $\log_{10} K_{50}$, i.e. p$K_{50}$) using a $K_d$ of 59 pmol litre$^{-1}$ obtained previously.[11] All data are expressed as mean (SEM) and displacement curves were drawn after correction for the competing mass of [$^3$H]PN200-110 for the whole curves.

## Results

All local anaesthetics displaced specific [$^3$H]PN200-110 binding in a dose-dependent manner (fig. 1A) with p$K_{50}$ values shown in table 1. The rank order of displacement was bupivacaine>amylocaine>lignocaine>prilocaine>procaine. There was a significant correlation between p$K_{50}$ and p (anaesthetic potency), p (conduction block), p (lipid solubility) and p (dose (mol kg$^{-1}$) required to reduce cardiac output by 50%).

Both ropivacaine optical isomers displaced [$^3$H]PN200-110 binding in a dose-dependent manner, with estimated p$K_{50}$ values of 3.005 (0.104) (987 μmol litre$^{-1}$) for R(+) and 3.036 (0.109) (920

*Table 1* Effects of local anaesthetics on [$^3$H]PN200-110 binding. Data are mean (SEM) ($n$=6)

| Local anaesthetic | p$K_{50}$ [mean $K_{50}$] (mmol litre$^{-1}$) |
|---|---|
| Procaine | 2.680 (0.039) [2.09] |

| Bupivacaine | 3.317 (0.019) [0.48] |

*Table 2* Correlation between p$K_{50}$ for [$^3$H]PN200-110 binding, local anaesthetic potency, relative conduction blocking potency, octanol:buffer partition coefficient and IC$_{50}$ for cardiac output. (Local anaesthetic and conduction blocking potency can be found in Strichartz and Berde.[4] Octanol:buffer partition coefficient at pH 7.4 and 25°C can be found Strichartz and colleagues[13])

| Correlation | $r^2$ | $P$ |
|---|---|---|
| p$K_{50}$ *vs* p (local anaesthetic potency) | 0.816 | 0.036 |
| p$K_{50}$ *vs* p (relative conduction blocking potency) | 0.843 | 0.028 |
| p$K_{50}$ *vs* p (octanol:buffer partition coefficient) | 0.872 | 0.020 |
| p$K_{50}$ *vs* p (IC$_{50}$ for cardiac output (mol kg$^{-1}$)) | 0.897 | 0.015 |

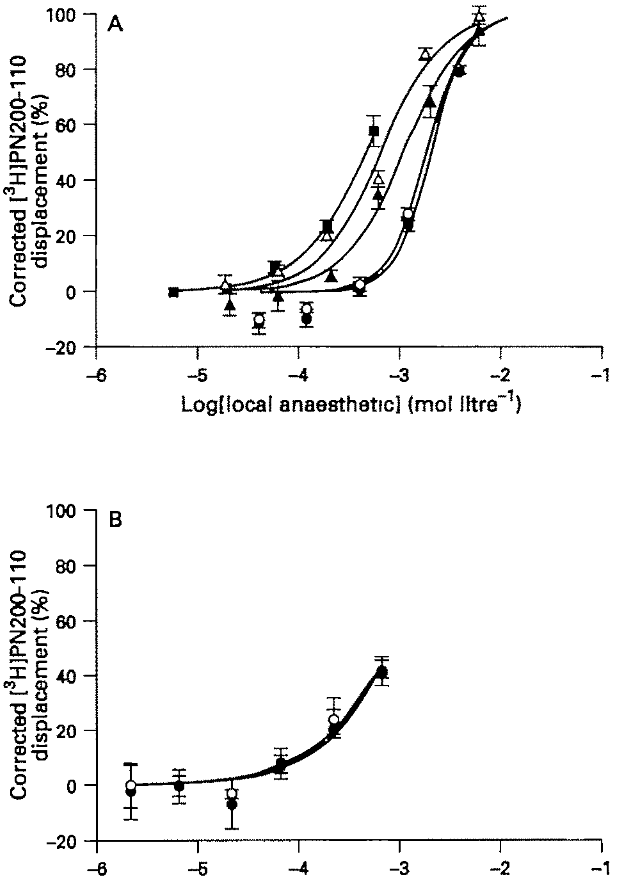

*Figure 1* A: Local anaesthetic agents dose-dependently displaced [$^3$H]PN200-110 binding to L-VSCC (●=procaine, ○=prilocaine, ▲=lignocaine, △=amylocaine and ■=bupivacaine). B: R(+) (●) and S(−) (○) ropivacaine displaced [$^3$H]PN200-110 binding in a dose-dependent manner but there was no stereoselectivity. Data are mean, SEM ($n$=5–6), expressed as corrected displacement where the curves have been corrected for the competing mass of [$^3$H]PN200-110.

$\mu$mol $\text{litre}^{-1}$) for S(−) (fig. 1B). In the case of ropivacaine where only 40% displacement was achieved, $pK_{50}$ values were estimated based on a theoretical 100% maximum displacement and were thus not included in any correlation calculations.

## Discussion

Local anaesthetics are well known to depress voltage-sensitive $Na^+$ channels, thereby blocking axonal conduction.[1–4] In this study we have demonstrated that a range of local anaesthetics dose-dependently inhibited [$^3$H]PN200-110 binding to L-type voltage-sensitive $Ca^{2+}$ channels. The concentration of anaesthetic producing 50% inhibition correlated with lipid solubility (octanol:buffer partition coefficient), anaesthetic potency, depression of cardiac output and conduction blocking potency.[4,13] In agreement with our data, Bolger and colleagues[7] reported that local anaesthetics displaced [$^3$H]nitrendipine binding (in an allosteric fashion) to rat brain and cardiac membranes, although they did not report a correlation between $K_{50}$ and partition coefficient. While we have not demonstrated this, we feel that local anaesthetic agents interact allosterically with the [$^3$H]PN200-110 binding site, and the "strength" of this allosterism is dependent on lipid solubility.

In addition to these radioligand binding studies there are several electrophysiological studies indicating that local anaesthetics depress high voltage-activated $Ca^{2+}$ currents (HVA-$I_{Ca}$), including DHP-sensitive ion movements.[5,6,8,9] Sugiyama and Muteki[9] suggested that inhibition of $Ca^{2+}$ influx through VSCC may contribute to spinal anaesthetic mechanisms as there is a good correlation between local anaesthetic potency and their ability to inhibit HVA-$I_{Ca}$. Moreover, lignocaine has been shown to inhibit depolarization evoked prolactin secretion from GH4C1 cells by inhibiting $Ca^{2+}$ influx, with an $IC_{50}$ value of approximately 0.25 mmol $\text{litre}^{-1}$.[14]

Also, a range of local anaesthetic agents have been reported to inhibit nicotinic receptor-mediated catecholamine release from bovine adrenal chromaffin cells.[15,16] Lee-Son and colleagues[3] found that local anaesthetics stereoselectively depressed neuronal $Na^+$ channels and Bolger and colleagues[7] also reported that the enantiomers of the experimental agent RAC-109 showed stereoselective inhibition of [$^3$H]nitrendipine binding in rat brain membranes. In this study we were unable to demonstrate a stereoselective interaction of ropivacaine enantiomers with rat cerebrocortical L-type VSCC. The lack of a stereospecific effect of ropivacaine enantiomers is difficult to explain and may question the importance of VSCC block in local anaesthetic action. However, as the isomeric differences in potency are usually small, the significance of these data is unclear. Collectively, our data suggest that L-VSCC block may be an additional mechanism of local anaesthetic action and support the general observation that L-type VSCC antagonists have antinociceptive properties.[17–19]

Accidental i.v. injection of local anaesthetic can precipitate cardiovascular collapse.[20,21] Cardiovascular toxicity of local anaesthetics results from a decrease in cardiac fast $Na^+$ channel activity.[20] In addition, modulation of cardiac $Ca^{2+}$ handling may also be implicated. Indeed, Lynch[22] suggested that depression of myocardial contractility produced by local anaesthetics may result from intracellular $Ca^{2+}$ release from the sarcoplasmic reticulum but not $Ca^{2+}$ entry, although cardiotoxic concentrations of local anaesthetics[21] seemed to depress $Ca^{2+}$ entry. In our study, a significant correlation between $pK_{50}$ and $pIC_{50}$ for cardiac output[4] was found, although it should be emphasized that in this study we used cerebrocortical membranes.

In conclusion, this study demonstrated an interaction between local anaesthetic agents and L-VSCC and this may contribute to the cardiotoxicity of local anaesthetic agents.

## Acknowledgement

We thank Astra Pharmaceuticals for provision of pure ropivacaine enantiomers.

# Effect of halothane on conventional protein kinase C translocation and down-regulation in rat cerebrocortical synaptosomes

H. C. HEMMINGS JR AND A. I. B. ADAMO

## Summary

Protein kinase C (PKC) is a key regulatory enzyme that has been implicated as a molecular target for the action of general anaesthetics. We have determined the effects of halothane on the translocation and down-regulation of conventional PKC (cPKC) by analysing the subcellular distribution of PKC activity, [$^3$H]phorbol-12,13-dibutyrate ([$^3$H]PDBu) binding and PKC immunoreactivity in intact rat cerebrocortical synaptosomes, a subcellular fraction that contains functional nerve terminals. Halothane alone (2.4 vol%) reduced membrane-associated ($P<0.05$) and increased cytosol ($P<0.01$) PKC activity, while phorbol-12-myristate, 13-acetate (PMA) 0.1 μmol litre$^{-1}$, a metabolically stable activator of PKC, reduced membrane ($P<0.01$) without altering cytosol PKC activity. Halothane and PMA in combination reduced membrane PKC activity to undetectable levels and reduced cytosol PKC activity ($P<0.01$). Halothane alone had no significant effects on the distribution of [$^3$H]PDBu binding, while PMA alone significantly reduced both membrane and cytosol [$^3$H]PDBu binding ($P<0.01$). Halothane and PMA in combination reduced membrane and cytosol [$^3$H]PDBu binding further, but this effect was not significantly different from the effect of PMA alone. Experiments using isoform-selective antibodies to PKC$\alpha$, PKC$\beta$ or PKC$\gamma$ demonstrated synergistic interactions between halothane and PMA in promoting translocation of the three conventional PKC isoforms from the cytosol to the membrane fraction of synaptosomes and down-regulation of their immunoreactivity. Halothane and PMA together reduced cytosol PKC$\alpha/\beta/\gamma$ immunoreactivity significantly more ($P<0.05$) than PMA alone. Halothane thus has two distinct actions on PKC in synaptosomes: activation of endogenous PKC activity and potentiation of activation-induced cPKC translocation and down-regulation. These potentially competing effects may underlie some of the conflicting results obtained with halothane on PKC-mediated processes in intact cells. (*Br. J. Anaesth.* 1997; **78**: 189–196)

**Key words**

Anaesthetics volatile, halothane. Enzymes, protein kinase C. Nerve, synaptosomes. Rat.

Protein kinase C (PKC) is an important family of protein kinases that regulates neuronal function.[1,2] Many studies have implicated PKC as a potential target for general anaesthetic effects in various tissues.[3–17] PKC exists as a number of structurally related isoforms distinguished by their regulatory domains and cofactor dependence[18–20]: the conventional PKC isoforms (cPKC: $\alpha$, $\beta1$, $\beta2$ and $\gamma$) are activated by Ca$^{2+}$, diacylglycerol and phorbol esters; the new PKC isoforms (nPKC: $\delta$, $\epsilon$, $\eta$ and $\theta$) do not require Ca$^{2+}$ but are activated by diacylglycerol and phorbol esters; and the atypical PKC isoforms (aPKC: $\zeta$, $\lambda$, $\mu$ and PKC$_\iota$) do not require Ca$^{2+}$ or diacylglycerol for activity and are not affected by phorbol esters.

Physiological activation of cPKC isoforms, which are abundant in mammalian brain,[19] occurs when diacylglycerol is generated in response to activation of cell surface receptors coupled to activation of phospholipase C or in response to Ca$^{2+}$-induced activation of phospholipase D.[1,21] Binding of diacylglycerol increases the affinity of cPKC for Ca$^{2+}$ and phosphatidylserine, facilitates cPKC translocation and binding to cell membranes, and increases cPKC catalytic activity.[22] Phosphorylation of specific proteins by activated PKC is the effector mechanism for regulation of several neuronal processes,[2] many of which are also sensitive to general anaesthetics, such as neurotransmitter release,[23] ion channel function[24] and neurotransmitter receptor desensitization.[25] On agonist-induced stimulation of a number of cell types, cPKC and nPKC, but not aPKC, isoforms[26] rapidly translocate from the cytosol to the membrane where they undergo proteolysis-mediated down-regulation in an isoform-specific manner.[27,28] The role of these important regulatory mechanisms in determining the ultimate effects of anaesthetics and other drugs on the PKC signalling pathway in specific tissues and cells is unknown.

Previous studies of general anaesthetic effects on PKC activity have yielded contradictory results. For example, halothane has been found to inhibit[13] or stimulate[14] purified brain PKC *in vitro*, and to

HUGH C. HEMMINGS JR*, MD, PHD, ANNA I. B. ADAMO, RMT, Department of Anesthesiology, Cornell University Medical College, New York, NY, USA Accepted for publication: October 14, 1996.

*Address for correspondence: Department of Anesthesiology, Box 50, LC-203, Cornell University Medical College, 525 East 68th Street, New York, NY 1002, USA.

stimulate PKC activity in brain cytosol,[6] in synaptosomes[15] and in intact neurosecretory cells.[9] These differences may be explained in part by variations in the conditions used to analyse PKC activity *in vitro*,[14] or by differences in the particular PKC isoforms present. PKC has been implicated in the effects of general anaesthetics on neurotransmitter release from PC12 cells,[9] prostacyclin production in endothelial cells,[16] protein phosphorylation in neuronal growth cones,[12] smooth muscle contraction,[10] hepatic blood flow[17] and loss of righting reflex in tadpoles.[11] Several of these studies inferred anaesthetic inhibition, rather than activation, of PKC activity based on indirect evidence. We now report evidence that halothane can potentiate cPKC translocation and down-regulation induced by phorbol ester treatment in synaptosomes. The results provide a potential mechanism for biphasic effects of halothane on PKC activity in intact cells: initial stimulation of PKC activity as a result of a direct effect on enzymatic activity,[15] followed by alterations in PKC-dependent processes caused by PKC translocation and down-regulation.

## Materials and methods

### SYNAPTOSOME PREPARATION AND INCUBATION

Synaptosomes were prepared from rat cerebral cortex by the method of Dunkley, Jarvie and Heath,[29] as described previously,[30] and were stored as pellets on ice for up to 4 h until use. Synaptosome pellets were resuspended to a protein concentration of 2 mg $ml^{-1}$ (determined by the method of Bradford[31] with bovine serum albumin as standard) in incubation medium containing the following (mmol $litre^{-1}$): NaCl 140, KCl 5, $NaHCO_3$ 5, $MgCl_2$ 1, D-glucose 10 and HEPES (4-(2-hydroxyethyl)-1-piperazine ethanesulphonic acid) 10, at pH 7.4 with NaOH containing 1 mg $ml^{-1}$ of fatty acid-free bovine serum albumin) equilibrated with 95% oxygen–5% carbon dioxide (v/v). After a 5-min incubation period in a shaking water bath at 37 °C to allow ion gradient re-equilibration, $CaCl_2$ 1 mmol $litre^{-1}$ was added to a 1-ml aliquot of synaptosomes. After another incubation period of 1 min, halothane, phorbol-12-myristate, 13-acetate (PMA) or drug vehicle (dimethyl sulphoxide; DMSO) was added where appropriate. Translocation reactions were carried out in 8.8 ml glass vials sealed with Teflon/silicone septa, through which liquid halothane (1–2 μl, either pure or diluted with DMSO, injected onto the side of the vial to vaporize) was injected directly with a Hamilton microsyringe. Final vapour phase halothane concentrations, which equilibrate by 2 min,[32] were measured in similar samples by gas chromatography.[33] The incubation was continued for another 10 min, after which the reaction mixtures were transferred rapidly to polycarbonate centrifuge tubes on ice and centrifuged at 9000×*g* for 5 min at 4 °C.

### SYNAPTOSOME FRACTIONATION

After incubation synaptosomes were fractionated by a modification of the method of Díaz-Guerra and colleagues.[34] The synaptosome pellet was lysed immediately in 2 ml of ice-cold hypotonic lysis buffer (HEPES 10 mmol $litre^{-1}$, pH 7.4, with NaOH, EGTA 1 mmol $litre^{-1}$, EDTA 1 mmol $litre^{-1}$, dithiothreitol 1 mmol $litre^{-1}$, leupeptin 1 μg $ml^{-1}$) by homogenization with a glass/Teflon homogenizer for five up-and-down strokes. The homogenate was centrifuged at 200 000×*g* for 15 min at 4 °C to yield supernatant ("cytosol") and pellet ("membrane") fractions, which were separated. The pellet fraction was resuspended in 1 ml of lysis buffer containing 0.5% (v/v) Nonidet P-40 by homogenization and incubated on ice for 30 min to extract PKC activity. An additional 1 ml of lysis buffer was added to dilute the detergent concentration, the pellet was centrifuged at 200 000×*g* for 15 min at 4 °C, and the supernatant fraction ("membrane extract") was removed. The cytosol and membrane extract fractions were then filtered through 1-ml (bed volume) columns of DEAE-cellulose (DE-52, Whatman) equilibrated in lysis buffer to remove endogenous PKC inhibitors[35] and detergent. The columns were washed with 4 ml of lysis buffer, followed by 2 ml of lysis buffer containing NaCl 0.1 mol $litre^{-1}$ to elute PKC activity. The samples containing PKC were then concentrated and their buffer changed to HEPES 10 mmol $litre^{-1}$, pH 7.5, with a Centricon-30 concentrator (Amicon, Inc., Beverly, MA, USA) The concentrated samples were adjusted to equal volumes and protein concentrations were measured by the method of Bradford.[31] Protein recoveries were comparable between the different treatments. Aliquots were stored frozen at −80 °C until analysis.

### PKC ACTIVITY

The activity of PKC in the synaptosome extracts was measured at 30 °C in a reaction volume of 0.1 ml containing HEPES 50 mmol $litre^{-1}$, pH 7.4, with NaOH, $MgCl_2$ 10 mmol $litre^{-1}$, bovine serum albumin 20 μg $ml^{-1}$ (fraction V; Baker, Phillipsburg, NJ, USA), dithiothreitol 0.1 mmol $litre^{-1}$, [$\gamma$-$^{32}$P]ATP 100 μmol $litre^{-1}$ (100–250 cpm $pmol^{-1}$; DuPont-NEN, Boston, MA), lysine-rich histone H1 0.2 mg $ml^{-1}$ (9.3 μmol $litre^{-1}$) (histone HL; Worthington Biochemical, Freehold, NJ, USA), an aliquot of synaptosome extract (protein 0.25–10 μg), $CaCl_2$ 1.5 mmol $litre^{-1}$, EGTA 1 mmol $litre^{-1}$ (free [$Ca^{2+}$]=500 μmol $litre^{-1}$), and small unilamellar lipid vesicles composed of bovine brain L-α-phosphatidylserine 20 μmol $litre^{-1}$ (PS; Avanti Polar Lipids, Alabaster, AL, USA), chicken egg L-α-phosphatidylcholine (PC; Avanti Polar Lipids) 80 μmol $litre^{-1}$ and 1,2-dioleoyl-sn-glycerol (Avanti Polar Lipids) 2 μmol $litre^{-1}$ prepared as described previously.[14] The reaction mixture, containing all assay components except ATP, was equilibrated for 5 min, after which reactions were initiated by addition of ATP and terminated after 5 min by addition of glacial acetic acid 10 μl. Histone phosphorylation was determined by the phosphocellulose paper method as described previously.[14] At least two concentrations of each synaptosome extract were analysed to ensure that the reaction was in the linear range. Each assay was performed in triplicate in the absence and presence of the selective PKC inhibitor peptide $PKC_{19-36}$[36] at 10 μmol $litre^{-1}$. PKC activity was defined as the difference between histone kinase activity in the absence or presence of the PKC inhibitor (1 unit of activity=1 pmol $min^{-1}$ of $^{32}P$ incorporation into histone H1). Background phosphorylation in the absence of histone HI as a result of endogenous substrates was negligible.

### 4β-[$^3$H]PHORBOL-12,13-DIBUTYRATE BINDING

Binding of the phorbol ester 4β-[$^3$H]phorbol-12,13-dibutyrate (PDBu) to PKC was determined at 37 °C in a reaction volume of 0.1 ml containing HEPES 50 mmol $litre^{-1}$, pH 7.4, with NaOH, $MgCl_2$ 10 mmol $litre^{-1}$, EGTA 1 mmol $litre^{-1}$, $CaCl_2$ 1.5 mmol $litre^{-1}$, PS 20 μmol $litre^{-1}$, PC 80 μmol $litre^{-1}$ and [$^3$H]PDBu 0.1 μmol $litre^{-1}$ (0.2 μCi; DuPont-NEN). The reaction was initiated by addition of [$^3$H]PDBu, incubated for 15 min (sufficient for equilibration of binding; data not shown), and terminated by addition of 4 ml of ice-cold Tris 20 mmol $litre^{-1}$, pH 7.5, with HCl, $CaCl_2$ 200 μmol $litre^{-1}$ and 20% (v/v) methanol, followed by rapid filtration through polyethyleneimine-treated[37] GF/C filters (Whatman, Hillsboro, OR, USA), and then by three washes of 2 ml each with the same buffer. Protein-bound radioactivity retained on the filters was quantified by liquid scintillation spectrometry in 4 ml of Bio-Safe NA scintillant (Research Products International Corp., Mount Prospect, IL, USA). Non-specific binding, determined by inclusion of non-radioactive PDBu 10 μmol $litre^{-1}$, was negligible. These assays were saturated with respect to [$^3$H]PDBu concentration and provided a quantitative assay of the phorbol ester receptor as an index of PKC.[38] Residual PMA from the preincubation does not affect subsequent binding of [$^3$H]PDBu to membranes as these subcellular fractions are subjected to chromatography and washing by centrifugation.[37]

In a separate series of experiments, the effect of halothane on equilibrium [$^3$H]PDBu binding to synaptosomes was analysed using a range of [$^3$H]PDBu concentrations (10–200 nmol $litre^{-1}$). The dissociation constant ($K_d$) and maximum number of binding sites (Bmax) were calculated from Scatchard plots using the Enzfit kinetic program (Elsevier-Biosoft, Cambridge, UK).

### PKC IMMUNOBLOT ANALYSIS

Immunoreactive PKC was measured by immunoblotting of synaptosome extracts separated by sodium dodecyl sulphate/polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to nitrocellulose membranes. Cytosolic and membrane extracts were prepared as described above, but were not subjected to detergent extraction or DE-52 column chromatography. Aliquots (protein 20–60 μg) of the crude extracts were separated by SDS-PAGE using a 10% acrylamide running gel.[39] Proteins were transferred from gels to 0.2 μm nitrocellulose sheets (Schleicher and Schuell, Keene, NH, USA) at 0.2 amp for 20 h by the method of Towbin, Staehelin and Gordon.[40] The nitrocellulose sheets were blocked with 2.5% (w/v) non-fat dry milk (Carnation) and 0.05% (v/v) Tween 20 in PBS buffer (potassium phosphate 10 mmol $litre^{-1}$, pH 7.4, NaCl 150 mmol $litre^{-1}$, 0.02% (v/v) sodium azide) overnight. After a brief rinse in immunoblot buffer (PBS containing 0.2% (v/v) Tween 20), the nitrocellulose transfers were immunoblotted for 2 h with one of three specific mouse monoclonal antibodies to PKC in immunoblot buffer: (1) an antibody to rat brain PKCα used at a dilution of 1:5000 (Transduction Laboratories, Lexington, KY, USA; #P16520); (2) an antibody to human PKCβ used at a dilution of 1:2500 (Transduction Laboratories, #P17720); and (3) an antibody to rat PKCγ used at a dilution of 1:5000 (Transduction Laboratories, #P20420). The nitrocellulose transfers were then incubated successively with immunoblot buffer three times for 10 min, with rabbit anti-mouse secondary antibody in immunoblot buffer for 1 h (1:500 dilution; Pierce; Rockford, IL, USA), with immunoblot buffer five times for 5 min, with $^{125}$I-labelled protein A (1 μCi $ml^{-1}$; Amersham) in 2.5% non-fat dry milk and 0.05% Tween 20 in immunoblot buffer for 1.5 h, and with immunoblot buffer overnight followed by twice for 5 min. The PKC immunoreactive bands were examined by autoradiography and quantified by scanning and analysis with a PhosphorImager autoradiography system (Molecular Dynamics, Sunnyvale, CA, USA).

Thymol-free halothane was a gift from Halocarbon Products (River Edge, NJ, USA). The PKC inhibitor peptide ($PKC_{19-36}$),[36] synthesized by the Rockefeller University Protein Sequencing Facility, was a gift from A. J. Czernik (Rockefeller University). Nonidet P-40, Tween 20 and sodium dodecyl sulphate were from Pierce Chemical Co. (Rockford, IL, USA). PMA and PDBu were from LC Laboratories (Woburn, MA, USA). Bovine serum albumin (fatty acid-free) was from Sigma (St Louis, MO, USA).

### STATISTICAL ANALYSIS

Statistical significance was assessed by analysis of variance with the Newman–Keuls multiple range test using the PHARM/PCS Pharmacological Calculation System, v. 4.2 (Springer-Verlag, New York, NY).

The studies were approved by the Cornell University Medical College Institutional Animal Care and Use Committee.

## Results

### PKC ACTIVITY

The relative content of PKC enzymatic activity in fractionated rat cortical synaptosomes is shown in table 1. The synaptosomal membrane fraction contained a higher specific activity of PKC (defined as $PKC_{19-36}$-sensitive histone H1 activity) than the

*Table 1* Subcellular distribution of PKC in synaptosome exposed to phorbol ester and halothane. Intact synaptosome were incubated at 37°C for 10 min in the presence of 0.2% DMSO (control) or PMA 0.1 μmol litre$^{-1}$ and/or 2.4 vol% halothane with 0.2% DMSO, followed by synaptosome subfractionation as described in materials and methods. Data for PKC activity and [$^3$H]PDBu binding are mean (SD) of three independent experiments with individual assays performed in triplicate. *Figure 1* Effect of halothane on equilibrium [$^3$H]PDBu binding to rat cerebrocortical synaptosomes as a function of [$^3$H]PDBu concentration in the absence (○=total binding; □=non-specific binding in the presence of PDBu 10 μmol litre$^{-1}$; △=specific binding) or presence (▽=total binding; ◇=non-specific binding in the presence of PDBu 10 μmol litre$^{-1}$; ●=specific binding) of 2.4 vol% halothane. Scatchard analysis yielded $K_d$ values of 18 (1.7) nmol litre$^{-1}$ and 16 (2.1) nmol litre$^{-1}$, and Bmax values of 3.9 (0.11) pmol/mg protein and 4.1 (0.16) pmol/mg protein in the absence or presence of halothane, respectively. A representative experiment, which was repeated four times, is shown.

cytosol fraction under basal conditions, which is consistent with the results of previous studies.[34 41] Treatment with phorbol esters has been shown to induce translocation of cytosolic PKC activity and down-regulation of membrane PKC activity in crude[27] and purified[34] synaptosomes. Exposure of intact purified synaptosomes to PMA 0.1 μmol litre$^{-1}$ for 10 min resulted in a significant reduction in membrane PKC activity with no change in cytosol PKC activity. Exposure of synaptosomes to 2.4 vol% halothane for 10 min also reduced membrane PKC activity, although not as much as PMA alone, but increased cytosol PKC activity. Exposure of synaptosomes to both PMA and halothane further reduced membrane PKC activity to undetectable levels and significantly reduced cytosol PKC activity compared with control, PMA alone or halothane alone.

### PHORBOL ESTER BINDING

Phorbol esters bind to the regulatory domains of and activate cPKC and nPKC, but not aPKC.[27 42] The effects of various treatments on the distribution of [$^3$H]PDBu binding sites in intact synaptosomes is shown in table 1. The cytosol fraction of rat cortical synaptosomes contained a four-fold excess of [$^3$H]PDBu binding sites compared with the membrane fraction. Exposure to PMA markedly reduced both membrane and cytosol [$^3$H]PDBu binding as a result of translocation and down-regulation.[27 34] The reduction in binding could be caused by residual PMA from the synaptosome preincubation competing with [$^3$H]PDBu binding, however, this effect has been reported to be reduced by anion exchange chromatography and washing before assay.[34] Exposure of synaptosomes to halothane had no significant effect on the subcellular distribution or amount of [$^3$H]PDBu binding. Treatment with a combination of both halothane and PMA reduced [$^3$H]PDBu binding to both the membrane and cytosol fractions, but this effect was not statistically different from treatment with PMA alone.

The effect of halothane on equilibrium binding of [$^3$H]PDBu was also assessed. A representative experiment is shown in figure 1. There was no significant difference between [$^3$H]PDBu binding to cerebrocortical synaptosomes in the absence ($K_d$=15 (SD 2) nmol litre$^{-1}$; Bmax=4.5 (1.1) pmol/mg protein) or presence ($K_d$=16 (7) nmol litre$^{-1}$; Bmax=4.7 (1.3) pmol/mg protein) of 2.4 vol% halothane ($n$=4).

### PKC IMMUNOREACTIVITY

Isoform-selective antibodies to PKC were used to determine the distribution of cPKCα, β and γ immunoreactive protein in control and treated synaptosomes by immunoblotting (fig. 2). All three

*Table 2* Subcellular distribution of conventional PKC isoforms in synaptosomes exposed to phorbol ester or halothane, or both. Intact synaptosome were incubated at 37°C for 10 min in the presence of 0.2% DMSO (control) or PMA 0.1 µmol litre$^{-1}$ and/or 2.4 vol% halothane with 0.2% DMSO, followed by synaptosome subfractionation as described in Materials and methods. Data are mean (SD) of one independent experiments with individual assays performed in triplicate. This experiment was repeated twice with similar results. cPKC isoforms (PKCα, $M_r$=82 000; PKCβ, $M_r$=80 000; PKCγ, $M_r$=80 000) were enriched in the cytosol fraction compared with the membrane fraction under control conditions (table 2). The relative amounts of the three cPKC isoforms in purified rat cerebrocortical synaptosomes detected with these antibodies (PKCα>PKCγ>>PKCβ) do not reflect the actual relative amounts caused by differences in antibody cross-reactivity. Treatment with PMA induced both translocation of all three isoforms of PKC from the cytosolic to the membrane fraction (evident in the significant increase in membrane-associated PKC) and down-regulation of PKC (evident in the reduced cytosolic and total PKC). The effect of PMA on PKCγ was less marked. This is consistent with a previous study that showed PKCγ to be less sensitive to PMA-induced translocation and down-regulation than PKCα or PKCβ.[27] Halothane caused a small reduction in cytosolic PKCα and an increase in cytosolic PKCβ. Combined treatment with halothane and PMA resulted in synergistic reductions in the cytosolic levels of all three, cPKC isoforms. There were no significant changes in membrane levels, although total immunoreactivity was reduced; this indicates an increase in both translocation and degradation of PKC, as proteolysis occurs primarily with the membrane bound, and not the cytosolic, form of the enzyme.

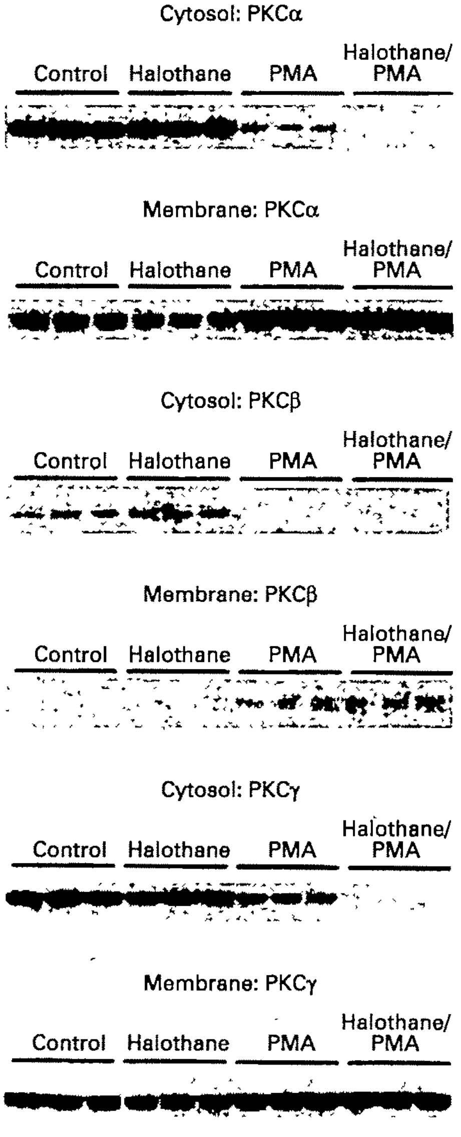

*Figure 2* Effects of halothane and phorbol ester on the subcellular localization of specific conventional PKC isoforms in rat cerebrocortical synaptosomes. Synaptosomes were incubated at 37°C for 10 min in the absence or presence of 2 4 vol% halothane, phorbol-12-myristate 13-acetate (PMA) 0.1 µmol litre$^{-1}$, or both, and separated into cytosolic and membrane fractions as described in the Materials and methods. Aliquots of each fraction (cytosol protein 20 µg; membrane protein 60 µg) in triplicate were separated by SDS-PAGE, transferred to nitrocellulose sheets and immunoblotted with antibodies to PKCα, PKCβ1 and PKCβ2, or PKCγ. PKC immunoreactivity was detected by the binding of $^{125}$I-labelled protein A and autoradiography (shown), and quantified by PhosphorImager analysis The portion of the immunoblot containing PKC immunoreactive bands ($M_r$=80–82 000) is shown for clarity; no other immunoreactive bands were identified.

## Discussion

Most neurones in the CNS contain the α, β and/or γ subspecies of the cPKC isoforms.[19,47] PKCα and

PKCβ are expressed in both CNS and peripheral tissues, while PKCγ is restricted to the brain and adrenal glands.[19] Within the CNS, PKCγ and PKCβ1 are found predominantly in nerve terminals and growth cones, while PKCγ and PKCβ2 are predominantly postsynaptic[19 43 44]; cortical synaptosomes contain PKCα, PKCβ and PKCγ.[44] The relative abundance and function of the nPKC or aPKC isoforms in synaptosomes have not been determined. Activation of PKC in synaptosomes or cultured neurones by diacylglycerol or tumour-promoting phorbol esters (long-acting agents that mimic the effects of diacylglycerol, which is rapidly metabolized) results in "translocation" of cPKC from the cytosol to the membrane fraction. Persistent activation of cPKC by diacylglycerol or phorbol esters results in "down-regulation" of PKC as a result of proteolysis with loss of enzyme activity and immunoreactivity. PMA causes an increase in particulate (membrane-associated) PKC activity ("translocation") at low doses (10 nmol litre$^{-1}$) followed by a dose- and time-dependent decrease in both cytosolic and particulate PKC activity ("down-regulation") in synaptosomes.[34]

Phorbol ester-induced translocation of cPKC in synaptosomes has been analysed previously by enzyme activity and phorbol ester binding measurements.[27 34] In this study we have compared the effects of phorbol ester or halothane, or both, on PKC translocation and down-regulation by three independent methods of PKC analysis: enzyme activity, phorbol ester binding and immunoblotting. Down-regulation of membrane PKC was the predominant effect of phorbol ester treatment observed for both PKC activity and [$^3$H]PDBu binding, while both translocation and down-regulation were observed for PKC immunoreactivity. Our results for the effects of phorbol ester on PKC activity and [$^3$H]PDBu binding generally agreed with those of previous studies.[27 34] Translocation of cPKC by phorbol ester has not been studied previously in synaptosomes by immunoblotting. However, comparable results have been reported by Chen and colleagues[42] in $C_6$ glioma cells in which 12-O-tetradecanoylphorbol 13-acetate 0.1 μmol litre$^{-1}$ induced a seven-fold increase in membrane PKCα and significantly reduced cytosolic PKCα. Of the three methods used to detect PKC, measurement of PKC immunoreactivity is the most direct method and least sensitive to artefacts,[28] although together they provide complementary information. Possible artefacts affecting measurement of PKC activity include the presence of endogenous PKC inhibitors,[35] non-linear reaction conditions, sub-optimal assay conditions, substrate accessibility and inadequate concentrations of the PKC inhibitor peptide. Possible artefacts affecting measurement of [$^3$H]PDBu binding include residual phorbol ester carried over from the preincubation with PMA (unlikely given the subcellular fraction preparation technique[34]) and the presence of endogenous phorbol ester binding competitors. Possible artefacts affecting measurement of PKC immunoreactivity include lack of antibody specificity and PKC degradation by proteolysis, the latter of which could also affect the two other methods. However, no immunoreactive breakdown products were detected in the immunoblots. Together these data indicate that caution is required in comparing the results of studies of PKC subcellular distribution determined by different methods.[28] The discrepancy between the activity measurements and [$^3$H]PDBu binding or immunoreactivity may reflect interactions between PKC and inhibitory regulatory protein(s) that modulate PKC activity in the membrane or cytosol, or both.[35]

We did not detect an effect of halothane on equilibrium [$^3$H]PDBu binding in synaptosomes. Activation of purified rat brain PKC by PDBu *in vitro* is also insensitive to halothane (unpublished observations). Our previous studies showed that halothane increases the sensitivity of PKC to activation by diacylglycerol, an endogenous PKC activator that binds to the same site in the regulatory domain of PKC as phorbol esters.[45] These results suggest that the interactions with PKC of phorbol esters and diacylglycerol differ in their sensitivity to halothane.

Halothane alone had no significant effects on PKC translocation or down-regulation measured by [$^3$H]PDBu binding or PKC immunoreactivity using the selective antibody to PKCγ. However, significant reproducible effects of halothane were observed on cytosol PKC activity and on cytosol PKCα and PKCβ immunoreactivity. Overall, the effects of 2.4 vol% halothane (which is close to its $EC_{50}$ for activation of purified PKC and is 2.3 times the MAC at 37 °C in rat[46]) on PKC distribution determined by the three methods were not consistent. In contrast, the combination of 2.4 vol% halothane and PMA 0.1 μmol litre$^{-1}$ consistently reduced cytosolic PKCα/β/γ immunoreactivity (increased PKC translocation) compared with treatment using PMA or halothane alone. The combination also reduced membrane PKC (increased PKC down-regulation) when measured by PKC activity, although this effect was not evident with [$^3$H]PDBu binding or the isoform-selective PKC antibodies. The enhanced translocation of PKC induced by halothane does not appear to involve a change in the ability of PKC to bind phorbol ester. This suggests that halothane stimulates the translocation process itself, perhaps by increasing the affinity of activated PKC for its membrane receptor.

We have shown previously that halothane and propofol stimulate purified PKC activity *in vitro*[14 45] and endogenous synaptosomal PKC activity *in situ*.[15] As prolonged stimulation of endogenous PKC with phorbol esters or diacylglycerol can promote cPKC translocation and down-regulation, we have analysed the effects of halothane on the subcellular distribution and down-regulation of cPKC in synaptosomes. Our results indicated that halothane alone had no significant effects on PKC translocation and down-regulation. The combination of halothane and the phorbol ester PMA resulted in significant potentiation of both translocation and down-regulation of synaptosomal PKC activity and immunoreactivity observed with PMA alone. These findings suggest that general anaesthetics may potentiate PKC translocation and down-regulation as a result of activation of PKC *in vivo*. Halothane thus has two distinct actions on the PKC signalling pathway in nerve terminals (synaptosomes): (1) activation of endogenous PKC activity that leads to increased phosphorylation of PKC substrates[15] and (2) potentiation of phorbol ester-induced cPKC translocation and down-regulation. The interactions between general anaesthetics and PKC are therefore complex; the ultimate outcome of these interactions depends on the tissue examined, PKC isoforms present, specific anaesthetic agent, dose and duration of anaesthetic treatment and possibly the coincident activation of PKC by endogenous PKC activators.

# *In vitro* neuromuscular effects of valproic acid

A. NGUYEN AND I. RAMZAN

**Summary**

The contribution of the anticonvulsant agent, valproic acid, to the interaction between neuromuscular blockers and anticonvulsants remains unclear. Therefore, this study was undertaken to examine the acute neuromuscular effects of valproic acid and its potential for interaction with neuromuscular blocking drugs. Phrenic nerve–hemidiaphragm preparations from rats were mounted in modified Krebs buffer, maintained at 37 °C and aerated with a 5% carbon dioxide–95% oxygen gas mixture. Phrenic nerves were stimulated with 0.1 Hz supramaximal pulses of 0.2-ms duration and the elicited tension of the hemidiaphragm was recorded in seven preparations in the presence of valproic acid 100, 500 and 1000 μmol litre$^{-1}$. In another six preparations, neuromuscular transmission was blocked completely with the non-depolarizing blocker tubocurarine 3 μmol litre$^{-1}$ and the hemidiaphragm muscle was stimulated directly (2 Hz and 2 ms duration). The effect of the anticholinesterase drug, neostigmine, on an established block induced by valproic acid 1000 μmol litre$^{-1}$ was also evaluated in five phrenic nerve stimulated preparations. The effect of valproic acid 100, 500 or 1000 μmol litre$^{-1}$ on suxamethonium- or atracurium-induced neuromuscular block was also evaluated. Valproic acid produced a mean of 29.7 (SEM 1.7) % and 24.7 (1.7) % block of indirectly or directly elicited muscle twitches. The concentration of valproic acid that caused half maximal paralysis did not differ between indirect (460 (59) μmol litre$^{-1}$) and direct (329 (35) μmol litre$^{-1}$) stimulation. Neostigmine 1–3 μmol litre$^{-1}$ failed to significantly alter the block of 19.8% induced by valproic acid 1000 μmol litre$^{-1}$. Valproic acid 100, 500 or 1000 μmol litre$^{-1}$ did not alter the concentrations of suxamethonium or atracurium needed to produce paralysis. These findings suggest that valproic acid does not produce significant block at the rat neuromuscular junction. The partial block that is produced is caused predominantly by a direct inhibitory effect on the muscle itself. (*Br. J. Anaesth.* 1997; **78**: 197–200)

**Key words**

Anticonvulsants, valproic acid. Neuromuscular block, atracurium. Neuromuscular block, suxamethonium. Neuromuscular block, interaction. Rat.

Anticonvulsant drugs, given either acutely or chronically, have been observed both clinically and experimentally to alter the paralysis induced by neuromuscular blocking agents. In patients receiving chronic therapy with phenytoin, resistance, as reflected by increased dose requirements and rapid recovery, has been observed to neuromuscular block induced by the non-depolarizing blocking agents pancuronium,[1] pipecuronium,[2] dimethyltubocurarine,[3 4] doxacurium,[5] rocuronium[6] and vecuronium.[7 8] Similar resistance towards pancuronium,[9] pipecuronium,[2] doxacurium[5] and vecuronium[10] has also been noted in patients receiving carbamazepine chronically. This resistance to neuromuscular blocking drugs is more pronounced when patients receive more than one anticonvulsant agent. Thus resistance to atracurium-induced block in patients with intractable seizure disorders was more pronounced when patients received carbamazepine chronically with either phenytoin or valproic acid compared with carbamazepine alone.[11] Similar additive effects during chronic combination therapy with anticonvulsants have been observed in patients with the non-depolarizing agents doxacurium[5] and pipecuronium[2].

In contrast, acute anticonvulsant use has been shown to potentiate the paralysis induced by neuromuscular blocking agents. Thus an acute 10 mg kg$^{-1}$ i.v. dose of phenytoin potentiated established neuromuscular paralysis induced by vecuronium in neurosurgical patients.[12] This effect was confirmed in another study where the neuromuscular blocking dose of vecuronium was reduced substantially in patients receiving phenytoin acutely.[13] Carbamazepine 10 mg kg$^{-1}$ i.v., administered acutely, potentiated the paralysis induced by either suxamethonium or atracurium in rats.[14] However, there is no information on other anticonvulsants, including valproic acid, administered acutely, either alone or in combination with phenytoin or carbamazepine.

Valproic acid, a broad spectrum anticonvulsant, is used widely, either alone or in combination with other anticonvulsants, in the treatment of primary generalized epilepsy or partial seizures.[15] Valproic acid therefore has the potential to interact with neuromuscular blocking drugs when it is used either acutely or chronically. As no information is available on the nicotinic actions of valproic acid, this study

was designed to examine the acute neuromuscular effects of valproic acid. Specifically, the *in vitro* neuromuscular effects of valproic acid alone and its influence on the neuromuscular blocking actions of a depolarizing blocker, suxamethonium, and a non-depolarizing agent, atracurium, were examined using the rat phrenic nerve–hemidiaphragm muscle preparation.

## Materials and methods

After approval by the University of Sydney Animal Care and Ethics Committee, triangular shaped hemidiaphragms with their attached phrenic nerves were obtained from 300–400 g male Sprague–Dawley rats. Each nerve–muscle preparation was mounted in a 50-ml organ bath containing modified mammalian Krebs solution of the following composition (mmol litre$^{-1}$): $Na^+$ 118, $K^+$ 6.2, $Ca^{2+}$ 1.4, $Mg^{2+}$ 0.9, $Cl^-$ 125.8, $H_2PO_4^-$ 1.2, $HCO_3^-$ 25 and glucose 11, maintained at 37 °C and bubbled with 5% carbon dioxide in oxygen. The phrenic nerve was stimulated supramaximally (approximately 2 V) at intervals of 0.5 s for 2 s (2 Hz) with rectangular pulses of 0.2-ms duration repeated every 10 s (train-of-four stimulation pattern). The resulting isometric muscle twitches were recorded using a Grass FT03 force displacement transducer and computerized data acquisition (MacLab) system. The first twitch response in the train (T1) was used to quantify neuromuscular block.

In the first experiment, organ bath concentration–response relationships for valproic acid alone were generated in seven nerve–muscle preparations by successive 100-μl additions of saline solutions of sodium valproate to generate organ bath concentrations of 5, 50, 100, 200, 400, 600, 800 and 1000 μmol litre$^{-1}$ of valproic acid. The preparations were exposed to each concentration for 10 min. Addition of valproic acid did not change the pH of the organ bath solution by more than 0.03 pH units. The direct effects of valproic acid on hemidiaphragm muscle itself was also studied in another six preparations by completely blocking neuromuscular transmission with tubocurarine 3 μmol litre$^{-1}$ and then supramaximally stimulating the muscle directly (5 V, 2 Hz and 2-ms duration). The concentration–response curve was then generated by adding successive amounts of valproic acid, as in the first study.

In a third study, designed to understand the mechanism(s) by which valproic acid produced its neuromuscular effect, neostigmine 1, 2 and 3 μmol litre$^{-1}$ was added to five preparations to examine its effect on established neuromuscular block induced by valproic acid 1000 μmol litre$^{-1}$. Indirect (phrenic nerve) stimulation was used to generate muscle twitches.

In the final experiment, the acute *in vitro* effects of valproic acid on neuromuscular block induced by either suxamethonium or atracurium were determined. The organ bath concentration–response relationships were generated for both suxamethonium and atracurium in the absence and presence of valproic acid 100, 500 or 1000 μmol litre$^{-1}$. Suxamethonium curves were produced in seven nerve–muscle preparations using freshly prepared saline solutions of the blocker to yield organ bath concentrations of 1–30 μmol litre$^{-1}$ while final bath concentrations of atracurium of 1–20 μmol litre$^{-1}$ were generated in six preparations using fresh saline diluted commercial injection solution. In each case, the concentration–response curves for each neuromuscular blocking agent alone was generated first, then the preparation was washed with fresh Krebs buffer until a stable baseline twitch response was re-established before the experiment was repeated with one concentration of valproic acid which was added just before the neuromuscular blocker. These interaction studies between valproic acid and suxamethonium or atracurium were undertaken with indirect (phrenic nerve) stimulation.

The organ bath concentration–response relationships for valproic acid, produced by both indirect (phrenic nerve) or direct (muscle) stimulation, were fitted to an Emax equation of the form:

$$E = E_{0} + (Emax - E_0) \times C / Cmax_{50} + C$$

where E and Emax=paralysis and maximum paralysis, respectively, $Cmax_{50}$=concentration causing 50% maximum paralysis, $E_0$=baseline paralysis which was not zero at the lowest drug concentration used, and $C$=organ bath concentration.

The pharmacodynamic variables for the neuromuscular effects of valproic acid using either indirect or direct stimulation were compared using the unpaired Student's *t* test. The neuromuscular effect of valproic acid alone or after addition of different concentrations of neostigmine were compared statistically using one-way analysis of variance (ANOVA). Suxamethonium or atracurium paralysis data in the absence or presence of valproic acid at the three concentrations (100, 500 or 1000 μmol litre$^{-1}$) were also fitted to the sigmoid Emax (Hill) equations mentioned previously, except that Emax was set to 100% and thus $Cmax_{50}$ represented the neuromuscular blocker concentration corresponding to 50% paralysis. All fittings were carried out using a personal computer based iterative procedure (PCNONLIN). Pharmacodynamic variables for the two neuromuscular blockers with or without valproic acid, respectively, were compared statistically using the paired Student's *t* test. Statistical significance was defined at $P<0.05$. All data are expressed as mean (SEM).

## Results

Using indirect (phrenic nerve) stimulation, valproic acid alone, in the concentration range 5–1000 μmol litre$^{-1}$, produced partial neuromuscular block of 29.7 (SEM 1.7) %, with a half-maximal concentration of approximately 450 μmol litre$^{-1}$. Direct muscle stimulation after complete block of neuromuscular transmission with tubocurarine produced a similar (24.7 (1.7) %) degree of block over the same valproic acid concentration range (table 1). Thus the concentration–response curves for valproic acid using either phrenic nerve or direct hemidiaphragm muscle stimulation were similar and superimposable (fig. 1).

*Table 1* Mean (SEM) maximum paralysis (Emax) and concentration causing half maximal paralysis (Cmax$_{50}$) for the neuromuscular blocking action of valproic acid using either indirect (phrenic nerve) or direct (muscle) stimulation. No significant differences

| Stimulation mode | $n$ | Emax (%) | Cmax$_{50}$) (μmol litre$^{-1}$) |
|---|---|---|---|
| Indirect | 7 | 29.7 (1.7) | 460 (59) |
| Direct | 6 | 24.7 (1.7) | 329 (35) |

*Table 2* Mean (SEM) Cmax$_{50}$ values for suxamethonium and atracurium in the absence or presence of various concentrations of valproic acid. No significant differences

| Valproic acid (μmol litre$^{-1}$) | $n$ | Suxamethonium (μmol litre$^{-1}$) | $n$ | Atracurium (μmol litre$^{-1}$) |
|---|---|---|---|---|
| Control | 7 | 7.8 (1.0) | 6 | 8.3 (0.9) |
| 100 | 7 | 8.2 (0.9) | 6 | 9.0 (0.7) |
| Control | 7 | 7.7 (0.6) | 6 | 7.2 (0.2) |
| 500 | 7 | 7.9 (0.7) | 6 | 8.0 (0.8) |
| Control | 7 | 7.3 (1.3) | 6 | 8.5 (0.2) |
| 1000 | 7 | 6.5 (0.6) | 6 | 8.9 (0.3) |

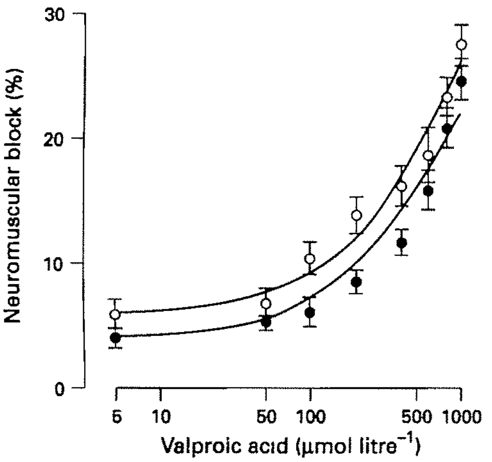

*Figure 1* Dose–response curves for valproic acid-induced neuromuscular block using indirect, phrenic nerve (○) or direct, hemidiaphragm muscle (●) stimulation. Data are mean, SEM, together with the predicted relationships ($n$=7 or 6, respectively).

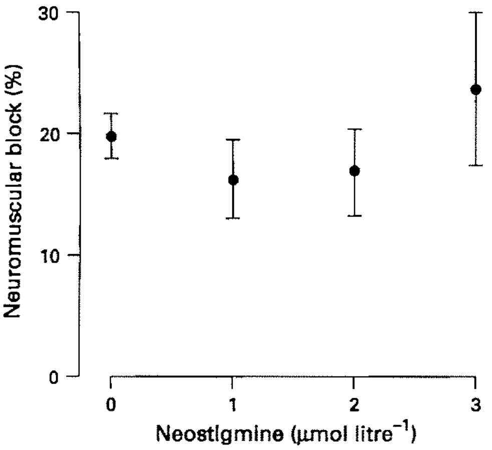

*Figure 2* Effect of the anticholinesterase, neostigmine, on neuromuscular block elicited by valproic acid 1000 μmol litre$^{-1}$ during indirect (phrenic nerve) stimulation. Mean, SEM ($n$=5). Neuromuscular block induced by valproic acid was not significantly altered after exposure to any concentration of neostigmine.

Neostigmine 1–3 μmol litre$^{-1}$ decreased neuromuscular block induced by valproic acid only transiently. Statistical analysis revealed that none of the three concentrations of neostigmine significantly reversed the paralysis induced by valproic acid (fig. 2).

Valproic acid 100, 500 or 1000 μmol litre$^{-1}$ when used with suxamethonium or atracurium failed to alter the concentration–response curve for either neuromuscular blocker. Thus the concentration of each blocker eliciting 50% block was the same in the absence or presence of valproic acid (table 2).

## Discussion

We have demonstrated that the anticonvulsant agent valproic acid exerted only a small neuromuscular blocking effect in the phrenic neve–hemidiaphragm preparation of the rat. At normal clinical doses (30–60 mg kg$^{-1}$) which yield concentrations in the range 200–700 μmol litre$^{-1}$, neuromuscular block was only 15–20%. Even at the highest concentration (1000 μmol litre$^{-1}$) only partial (29.7%) block was observed. Thus valproic acid, unlike the anticonvulsant phenytoin, is unlikely to depress neuromuscular function or potentiate neuromuscular blocking agents when surgical patients receive valproic acid acutely either before or during neurosurgical procedures. The small neuromuscular effect noted with valproic acid appears to be caused by a direct inhibitory effect at the muscle or postsynaptic effects. This is reflected in similar neuromuscular dose–response curves when the preparations were stimulated either indirectly via the nerve or directly via the muscle. Thus the predominant effect of valproic acid seems to be at the level of the muscle itself, where it appears to reduce muscle sensitivity. This postulated mechanism is also consistent with the lack of an effect of the anticholinesterase, neostigmine, on neuromuscular block elicited by valproic acid. If valproic acid was producing its effect via a depolarizing mechanism, then neostigmine would deepen the valproic acid-induced block. In contrast, if a non-depolarizing effect was being produced by valproic acid, then reversal of paralysis would have been observed. No such effects were observed when neostigmine was tested in the phrenic nerve–hemidiaphragm preparation.

That valproic acid was not producing its small neuromuscular effect via either a depolarizing or non-depolarizing mechanism is supported further by the results of interaction studies with suxamethonium and atracurium. Thus despite the use of higher than therapeutic concentrations of valproic acid, there were no alterations in the concentration–response curve for either suxamethonium or atracurium. This also indicates an alternative mechanism for the neuromuscular effect of valproic acid.

Previous *in vitro* rat experiments have shown that several other anticonvulsants, including phenytoin, trimethadione, phenobarbitone and ethosuximide produced neuromuscular block at the rat neuromuscular junction.[16] Similar results have been obtained with these agents at the frog neuromuscular junction.[17] No previous studies, however, either in patients, at the rat neuromuscular junction or in other species, have examined the neuromuscular effects of valproic acid.

The acute neuromuscular effects of valproic acid demonstrated in this study are opposite to the effects noted with chronic use of anticonvulsant drugs, including valproic acid. The chronic effects are more likely to result from enzymatic metabolism of neuromuscular blockers resulting from enzyme induction after chronic exposure to anticonvulsants. The acute neuromuscular effects of valproic acid, as observed in this study, reflect the directs effects of this anticonvulsant agent at the neuromuscular junction itself.

REVIEW ARTICLE

# Cytokines in anaesthesia

P. SHEERAN AND G. M. HALL

Cytokines are a heterogeneous group of proteins, variously termed lymphokines, monokines, interleukines and interferons, which act on cell surface receptors to regulate and modify cell growth, maturation and repair. In addition to their longer-term effects on cell growth and differentiation, cell-mediated host–defence mechanisms and chronic diseases such as rheumatoid arthritis, cytokines also mediate several acute effects such as the inflammatory response. Cytokines are produced from activated leucocytes, in particular monocytes, and also from activated fibroblasts and endothelial cells.[12] Activation of these cells is one of the earliest cellular responses to tissue injury and is associated with release of a variety of inflammatory mediators, including cytokines, arachidonic acid metabolites, complement split products, lysosomal enzymes and oxygen-free radicals. Cytokines derived from mononuclear phagocytes mediate non-specific immune responses and some parts of the metabolic response to injury.[11] They have local and systemic effects, both mediated by activation of specific receptors. The other principal stimulus to the metabolic response to injury is afferent neuronal input from the injured or operative site.

This review is confined to activation of the cytokine network and the acute phase response found in surgery and trauma. Chronic stimulation of cytokine secretion, for example in sepsis, has been discussed recently.[18]

## Discovery of cytokines

Early studies of cytokines from 1950 to 1970 involved the description of numerous protein factors produced by different cells that mediated particular functions *in vitro*. Evidence implicated thymus-derived T lymphocytes as the cells which interacted specifically with antigen to release these protein factors, which were termed lymphokines to show their origin and function. Simple cell culture supernatants influenced the behaviour of target cells in many ways, indicating that cellular immune functions were regulated by soluble factors. It was at this time that antiviral interferons, fever-producing pyrogens and macrophage-activating factor were discovered.

The second phase of cytokine research involved the purification and characterization of many individual cytokines. It was realized that diverse effects were often mediated by the same peptide, and that cytokines were synthesized principally by leucocytes to act primarily on other leucocytes and thus were termed interleukins. However, preparations of cytokines at this time were often impure and many of the cytokine antibodies available were not specific. This hampered identification of, and distinction between, various cytokines.

In the past decade, molecular cloning and the production of highly specific, neutralizing antibodies, have resulted in the precise identification of the structure and properties of individual cytokines. All cytokines interact with specific receptors and it is the elucidation of the structure of these receptors and the signalling pathways used that are beginning to provide mechanisms and explanations for the often bewildering and diverse biological effects of this group of molecules.[66]

## Characteristics of cytokines (modified from Molloy, Mannick and Rodrick[86] and Abbas, Lichtman and Pober[1])

Cytokines have the following properties:

(1) They are low molecular weight (<80 kDa) secreted proteins, often glycosylated.

(2) They are involved in immunity and inflammation where they regulate the amplitude and duration of response. Cytokine secretion is a brief, self-limiting event.

(3) Cytokines are extremely potent, generally acting at picomolar concentrations.

(4) Cytokines, in common with other polypeptide hormones, initiate their action by binding to specific receptors on the surface of the target cell. Cytokines tend to be paracrine (act on a nearby cell) or autocrine (act on the same cell), rather than endocrine (secreted into the circulation to act on a distant cell).

(5) Activation of surface receptors leads ultimately to a change in the pattern of cellular RNA and protein synthesis, and to altered cell behaviour.

(*Br. J. Anaesth.* 1997; **78**: 201–219)

**Key words**
Polypeptides, cytokines. Immune response, cytokines.

(6) Cytokines act on many different cell types—pleiotropism.

(7) Cytokines often influence the synthesis and action of other cytokines.

(8) Cytokines often have multiple effects on the same cell.

(9) Cytokines act as regulators of cell division for many target cells, that is as growth factors.

(10) The response of a cell to a given cytokine is dependent on the local concentration of the cytokine, cell type and other cell regulators to which it is concomitantly exposed.

Most cytokines are synthesized as they are required and are not stored. However, some cytokines are presynthesized and stored in cytoplasmic granules. For example transforming growth factor-beta1 (TGF-β1) is stored in alpha granules of platelets and released when stimulated by thrombin.[9] Other instances of cytokines stored in this way include tumour necrosis factor-α (TNF-α) in some mast cells,[56] granulocyte/macrophage colony stimulating factor (GM-CSF), platelet factor 4 (PF-4) and platelet derived growth factor (PDGF).[69] Presynthesized cytokines can also be stored as membrane proteins, for example TNF-α, interleukin 1β (IL-1β), endothelial growth factor (EGF) and transforming growth factor α (TGF-α)[78] or form complexes with cell surface binding proteins or extracellular matrix, for example transforming growth factor β (TGF-β), macrophage inflammatory protein 1β (MIP-1β) and interleukin-8 (IL-8).[101 133] This serves as an immediate source of cytokine when the tissue matrix is broken down during injury and repair.

## Role of cytokines in the immune response

The immune response is divided into the non-specific (or innate) and specific (or acquired) immune response. Non-specific defence includes physical barriers, several phagocytic cells and various blood-borne molecules. This defence mechanism is present before exposure to foreign macromolecules. It is not enhanced by exposure and it does not discriminate between foreign substances.

In contrast, the specific immune response is induced by exposure to foreign macromolecules. It is specific for each macromolecule and increases in magnitude with each successive exposure. In essence, the specific immune response serves to enhance the non-specific immune response.

### NON-SPECIFIC IMMUNITY

When a foreign substance enters the body, the initial attempts to eliminate it come from an inflammatory response led by neutrophils and macrophages. In engulfing the foreign molecules, some of these cells extrude foreign antigen onto the cell surface, so becoming antigen presenting cells (APC). They are involved in the initial stages of specific immunity and also synthesize and release cytokines. Other active products of these cells are proteolytic enzymes and reactive oxygen species.

In conjunction with other cells of the immune system, such as natural killer (NK) cells and T helper lymphocytes (see below), macrophage activation is critically dependent on cytokine production. The complement system also plays a supportive role in the non-specific immune response. These proteins are synthesized in the liver and, when activated, augment phagocytosis and can cause direct cytolysis.

Other cells involved in this non-specific first line of defence are NK cells and lymphokine-activated cells (LAK cells). NK cells are large granular lymphocytes that destroy cells by direct contact, in a non-major histocompatibility complex-dependent manner. They can be regarded as cytotoxic lymphocytes (CTL) or CD8+ lymphocytes, without a T cell receptor for antigen, that is they have not resulted from overt antigenic stimulation. These cells were previously termed null cells, as they did not express markers for either T or B cells. While much is still not known about this group of lymphocytes, they kill their target cells by mechanisms similar to the CTL.

The major histocompatibility complex (MHC) is a region of polymorphic genes expressed on the short arm of chromosome 6, whose products (termed MHC-encoded proteins or MHC antigens) are expressed on the surfaces of a variety of cells.[87 97] Thus the NK cell response, by acting in a non-MHC-dependent manner, is not antigen-dependent. NK cells also release TNF and interferons. In response to IL-2 and IL-12, NK cells are a potent source of interferon-γ (IFN-γ); in T cell deficient mice, IFN-γ from NK cells activates macrophages to provide a cellular response. LAK cells are formed when NK cells are exposed to high concentrations of IL-2 or interferon-α (IFN-α). They attack a broader range of target cells than NK cells, again in a non-specific manner. NK cells act in the initial response to a foreign antigen, attempting to eradicate the infected cell before the appearance of specific cytotoxic lymphocytes. If the stimulus is large enough, as in graft *vs* host reactions, NK cells differentiate into LAK cells, which, in common with other activated cells release cytokines to maintain the response.

### SPECIFIC IMMUNITY

Specific immune responses occur after exposure to antigens, through a chain of events that results in highly specific antibodies (humoral immunity) or production of a specific set of lymphocytes (cell-mediated immunity).

The antigen receptors of B lymphocytes (bursa or bone-marrow derived lymphocytes) are membrane-bound forms of antibodies. Antigen binds to these membrane-bound antibody molecules to initiate the sequence of B cell activation, which culminates in the production of effector cells that actively secrete antibody molecules (humoral immunity).

T lymphocytes play a central role in specific immune responses to protein antigens. T lymphocytes can recognize and respond to foreign antigen only when it is presented in a complex with a self MHC molecule, on the surface of an appropriate APC cell. There are two different types of MHC molecule, class I and class II. Any given T lymphocyte can only recognize foreign antigen bound to either a class I or class II MHC molecule.

Two types of T lymphocytes occur, T helper cells and cytolytic T cells. They can be differentiated from each other because they express different membrane proteins. These different membrane proteins can be recognized by antibodies, or more specifically a "cluster" of monoclonal antibodies. These membrane proteins are termed CD molecules or "cluster of differentiation" molecules. Most helper T cells express a surface protein termed CD4, and most cytolytic T lymphocytes express a different marker termed CD8. Apart from the invaluable role the CD antigens play in identifying, isolating and analysing the specificities of different lymphocyte subsets, CD antigens are also important in promoting cell–cell interactions and adhesion, and in transducing signals leading to lymphocyte activation.

Peptide fragments derived from extracellular protein (exogenous antigens), following phagocytosis, are expressed on the cell surface bound to class II MHC molecules and are recognized by CD4+ T cells (+ denotes activated cell). These CD4+ T cells are usually T helper lymphocytes. In contrast, peptides derived from proteins synthesized in the cell (endogenous antigens) from foreign genetic protein (viral), generally are expressed with class I MHC molecules. These are recognized by CD8+ T cells, which are usually cytolytic T lymphocytes. Therefore, whether an antigen is endogenous or exogenous determines the type of specific immune response.

There is a subset of T cells that may also inhibit immune responses, termed suppressor T cells. A major problem in the study of this group of lymphocytes has been inability to purify these cells in adequate numbers to analyse their response patterns and functions. Consequently, even basic questions remain unresolved. It seems the inhibitory effects of these suppressor lymphocytes may be mediated by suppressor proteins which are soluble receptors belonging to this lymphocyte subset, hence their antigenic specificity. What is clear is that some antigens can stimulate a group of lymphocytes whose principal role is one of down-regulation of major immune responses.

The T helper lymphocyte (Th cell) responds to the antigen on the surface of the APC. When activated, Th lymphocytes produce cytokines, which increase the number of cytokine receptors on cell membranes, resulting in further development of these T lymphocytes. Cytokines control the subsequent direction and development of T helper subsets, namely Th1 subset and Th2 subset, with each subset secreting discrete cytokine profiles. Thus bacterial stimuli activate cells of the non-specific immune system to produce IFN-γ, IL-2 and IL-12 and to drive Th1 development and cell-mediated immunity. Conversely, production of IL-4 early in the response favours Th2 development and an allergic/humoral immune response.[102]

Development of the appropriate Th subset is important because some pathogens are controlled most effectively by either a predominantly cell-mediated (Th1) or an allergic or antibody-mediated humoral immunity (Th2) type response.[102] Maturation of the T helper subsets is cytokine dependent, Th1 is dependent on IFN-γ production, which is induced by IL-12, and predominantly produces further IFN-γ and IL-2. Th2 lymphocyte development is dependent on early IL-4 production and, on activation, produces IL-4, IL-5, IL-10 and IL-13, and little or no IFN-γ.

The concept of Th1 cytokines (IFN-γ, IL-2) stimulating Th1 lymphocyte development and suppressing Th2 lymphocyte activity, and Th2 cytokines (IL-4, IL-10, IL-13) stimulating Th2 development and IgE production and suppressing Th1 lymphocyte and IFN-γ activity may be one mechanism for "suppressor T cell" activity. Transforming growth factor-β (TGF-β), an inhibitory cytokine, is a powerful inhibitor of T and B cell proliferation, and any cell that produces excess amounts of this cytokine can play a role in suppressor T cell activity.

Thus cytokines play a major role in promoting or limiting Th1 or Th2 development, and also in initiating specific immune responses to various pathogens.

### CELL ADHESION MOLECULES (CAM)

Together with the cytokines, CAM function as the molecular mechanism by which cells of the immune system communicate with each other, and appear on the surfaces of neutrophils and endothelial cells very early in an inflammatory response.[126] Cell adhesion molecules are cell surface proteins involved in the binding of cells either to each other, to endothelium or to the extracellular matrix. They attract infiltrating phagocytic cells to the site of injury, in conjunction with release of chemoattractant agents (e.g. IL-8 and monocyte chemoattractant protein-1, MCP-1). Cell adhesion molecules primarily determine the migration route of cells, although they have other functions. Increased values of CAM may represent an earlier indicator of an activated immune response than an increase in cytokine secretion. The main groups of cell adhesion molecules are the selectins and immunoglobulin superfamily (IGSF). Selectins such as endothelial leucocyte adhesion molecule-1 (ELAM-1) act in the initial phases of cell adhesion to capture leucocytes from the circulation onto the vascular endothelium. This is only a transient interaction unless other adhesion pathways are activated.

IGSF adhesins include intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). These are ligands for β1 and β2 integrins. This combination of ligand–integrin pairs is involved in establishing firm adhesion after the initial selectin-mediated adhesion. These pairs are also involved in the transfer of cells across endothelium to sites of inflammation.

## Classification of cytokines

The principal biological actions of a particular cytokine fall into four broad categories, although many cytokines may function in more than one of these categories:

### (A) MEDIATORS OF NATURAL IMMUNITY

This group includes those cytokines that protect against viral infection and those responsible for the protective inflammatory response against bacteria, such as TNF-α, IL-1, IL-6 (minor role) and the chemokines (cytokines whose principal effect is one of chemotaxis of leucocytes). Also included in this group are IL-5 (responsible for eosinophil chemotaxis) and IL-8 (responsible for neutrophil chemotaxis). Chemokines can be regarded as a distinct class of cytokine, in their own right.

### (B) REGULATION OF LYMPHOCYTE ACTIVATION, GROWTH AND DIFFERENTIATION

Some cytokines are involved in the development of specific subsets of lymphocytes. The subset determines the type of immune response, namely IL-2 preferentially favours Th1 lymphocyte development and a cell-mediated immune response; IL-4 favours Th2 lymphocyte development and an allergic response (IgE production, mast cell development and adhesion molecule production responsible for eosinophil and basophil chemotaxis). TGF-β is an "anti-cytokine", in that it largely counteracts the effects of the proinflammatory cytokines. It is included in this group of cytokines because it antagonizes many lymphocyte responses such as CTL maturation and activation of macrophages.

These cytokines are secreted in response to antigen recognition by lymphocytes, mediating the activation phases of specific immune responses. Most of the cytokines are produced by T cells, especially antigen-specific CD4+ T lymphocytes. Other examples include IL-1, IL-6, IL-12, IL-7, IL-9 and TNF.

### (C) REGULATORS OF IMMUNE-MEDIATED INFLAMMATION

These cytokines activate non-specific inflammatory cells in response to specific antigen recognition by T lymphocytes. IFN-γ activates macrophages to phagocytose microbes and, with other cytokines regarded as macrophage activating factors (MAF), can also kill tumour cells. IFN-γ is the principal MAF, others include GM-CSF, and to a lesser extent IL-1 and TNF. IFN-γ also stimulates the cytolytic activity of NK cells, activates vascular endothelium and promotes Th1 development. Other cytokines included in this group are the "pro-inflammatory" cytokines IL-1 and TNF and the "anti-inflammatory" cytokines TGF-β, IL-4 and IL-10.

### (D) STIMULATORS OF IMMATURE LEUCOCYTE GROWTH AND DIFFERENTIATION

This group includes cytokines already classified in some of the above groups; IL1, IL-3, IL-5 and IL-6. Immune and inflammatory reactions, which consume leucocytes, also elicit production of new leucocytes to replace inflammatory cells. These cytokines are collectively termed colony-stimulating factors (CSF), and specifically include granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF) and granulocyte/macrophage colony-stimulating factor (GM-CSF).

## Cytokines relevant to anaesthesia

Cytokines play a central role in the acute inflammatory response initiated by trauma or infection. IL-1, TNF-α and IL-6 have local and systemic effects, which attempt to limit injury and the spread of infection, and provide a suitable environment for tissue healing and repair. Local effects include migration of neutrophils, lymphocytes and monocytes into inflamed areas as a result of increased permeability of the endothelium, adhesion molecules and chemotactic cytokines (chemokines) such as IL-8. Systemic changes include neutrophilia, fever production, adrenocorticotrophic hormone release, a decline in circulating zinc and iron, and synthesis of acute phase proteins by the liver. These are all components of the acute phase response, a homeostatic response to major physiological insults such as trauma, infection or surgery.

There are numerous stimuli inducing release of TNF-α and IL-1; the most potent stimulus is the lipopolysaccharide or LPS component of endotoxin. Cytokines also induce further cytokine production, for example both IL-1 and TNF-α are potent inducers of IL-6, with IL-1 30 times more potent than TNF.

The physiology of each cytokine is outlined below.

### TUMOUR NECROSIS FACTOR (TNF)

TNF is secreted as a pro-hormone and cleavage results in a 157 amino acid polypeptide.[86] In common with all cytokines, interaction with a specific receptor is necessary for a biological response. Its potency is such that occupancy of as little as 5% of its receptors produces a biochemical response.[136] It exists as two distinct polypeptides, TNF-α and TNF-β, which are antigenically different, yet bind to the same receptors and produce similar, but not identical effects. It shares a central role with IL-1 in initiating the cascade of inflammatory mediators, cytokines, complement, and activation of leucocytes, lymphocytes and macrophages that make up the immune response. Overproduction of TNF production can be disastrous to the host and is seen in such pathological conditions as cachexia,[17] autoimmune disorders[109] and meningococcal septicaemia.[54 141]

The two TNF proteins produce a diversity of effects because of (i) the ubiquity of their receptors, (ii) their ability to activate multiple signal transduction pathways and (iii) their ability to induce, or suppress, the expression of a vast number of genes coding for growth factors, cytokines, transcription factors, receptors, inflammatory mediators and acute phase proteins.[140]

Just as there are two forms of TNF, α and β, so there are two forms of TNF receptor, TNFR-I and TNFR-II (see below). Both receptor types show equally high affinity binding for either TNF-α or

TNF-β. There is also present in serum soluble TNF binding proteins that are in essence TNF receptors not bound to cell membranes. These soluble receptors compete with the bound TNF receptors for TNF and therefore limit the activity of the cytokine.[54 108]

### INTERLEUKIN-1 (IL-1)

IL-1 was known by several names until amino acid sequencing revealed a closely related family of polypeptides. IL-1 exists in two forms, IL-1α and IL-1β, that are produced from two separate genes, yet activate the same receptors with equal affinity.

IL-1 has more inflammatory and immunoenhancing potential than TNF. It stimulates myelopoesis directly, and also indirectly via several myelopoeitic growth factors, including GM-CSF. It is an endogenous pyrogen, increasing synthesis of prostaglandin $E_2$ ($PGE_2$) in the anterior hypothalamus and is involved in the development of anorexia.[86]

In common with TNF, the main stimulus for IL-1 release is LPS, endotoxin antigen. Indeed, both TNF and IL-1 share many functions and nearly all of the activities of TNF and IL-1 are enhanced when they are administered together.[39] IL-1 and TNF have a wide variety of biological activities and play an important role in stimulating T and B cells, in addition to macrophages. TNF is chemotactic for polymorphonuclear leucocytes and activates respiratory burst and degranulation of these cells releasing oxygen-derived free radicals, whereas IL-1 does not. Both have antigenic activity, causing release of prostaglandins, IL-6 and IL-8 from monocytes, and stimulate endothelial cells to produce prostaglandins, IL-6 and tissue factor III, which may play a role in disseminated intravascular coagulation. TNF and IL-1 can elicit production of tissue factor by endothelium and monocytes, down-regulating expression of thrombomodulin simultaneously. Therefore, an inflammatory reaction shifts the haemostatic balance towards coagulation and away from anticoagulation.[41]

IL-1 mediates its activities through receptors on the cell membrane, either IL-1R type I or IL-1R type II. They show 25% structural homology, and in general IL-1α binds to IL-1R type I and IL-1β binds to IL-1R type II.

It has been shown recently that all the biological effects of IL-1 can be attributed to the receptor IL-1R type I transducing a signal. The function of the IL-1R type II receptor is unknown, but it may serve as a precursor for the soluble receptor form, thus antagonizing and regulating the activity of IL-1.[112 128]

### INTERLEUKIN-6 (IL-6)

Together with TNF and IL-1, IL-6 is one of the mediators of the acute phase response. In addition to its role in the inflammatory response, it plays an important part in host defence, immune responses and haematopoiesis. Over-expression or chronic activation of IL-6 is implicated in diseases such as systemic lupus erythematosus and rheumatoid arthritis. IL-6 is expressed by several normal and transformed cell types and its production is up-regulated by numerous signals, including mitogenic and antigenic stimulation, lipopolysaccharide (LPS), IL-1, IL-2, TNF, interferon, platelet derived growth factor (PDGF) and viruses.

IL-6 exerts its activity through binding to a high affinity receptor complex comprising an 80-kDa receptor protein (IL-6R) and a 130-kDa signal transducing glycoprotein (gp-130).[61] IL-6 binds to the receptor IL-6R with only low affinity. In the presence of gp-130, IL-6 binds to the receptor IL-6R with high affinity, resulting in signal transduction. In the absence of IL-6R, IL-6 does not bind to gp-130; however, in the absence of IL-6R and the presence of soluble IL-6 receptor (sIL-6R), high affinity binding with gp-130 occurs and signal transduction is triggered. This is in direct contrast to binding between TNF and the soluble TNFR, where the complex renders TNF inactive.

The regulation and physiological significance of this soluble IL-6R and its binding with IL-6 are poorly understood, but significantly increased serum concentrations of this protein have been found in some pathological states, such as multiple myeloma, adult T cell leukaemia and HIV infection. Soluble glycoprotein 130 has also been identified in serum and it is probable that this soluble protein regulates production of IL-6.[95]

### INTERLEUKIN-2 (IL-2)

IL-2 is the major autocrine and paracrine growth factor for T lymphocytes and the quantity of IL-2 synthesized determines the size of the T cell-dependent immune response. IL-2 also stimulates production of other T cell-derived cytokines, IFN-γ and TNF-α. IL-2 and IFN-γ encourage the development of the cytotoxic Th1 subset of T lymphocytes and are responsible for cell-mediated immunity. After injury $PGE_2$ is produced by inhibitory monocytes and results in down-regulation of IL-2 synthesis.[23] It is this decrease in IL-2 production that is the most striking abnormality that has been observed in trauma-induced immunodeficiency.[44] IL-2 also augments the function of neutrophils and macrophages, stimulates growth and cytolytic function of NK cells, and is a growth factor for B cells.

The biological activities of IL-2 are mediated by binding to a multi-molecular cellular receptor, namely, IL-2Rα, IL-2Rβ and IL-2Rγ. Full details of signal transduction are not known but the IL-2Rγ receptor is common to several other cytokine receptors. As with other cytokine receptors, a soluble form of IL-2Rα exists. Its function is unclear, but it is an indication of T cell activation and may be able to predict the onset of transplant rejection.[142]

IL-2 has shown promise as an anticancer drug because it stimulates LAK cells and tumour-infiltrating lymphocytes (TIL).[117 148] High doses of IL-2 improved survival in a murine model of burns and sepsis.[57] Furthermore, low doses of IL-2 combined with indomethacin improved survival and restored normal immune response in this murine model.[65]

Antibodies to IL-2 and IL-2 receptors may have potential in the prevention of allograft rejection and suppression of auto-immune disease.

### INTERLEUKIN-3 (IL-3)

IL-3 acts as a mast cell colony-stimulating factor (CSF) and a CSF on haematopoietic cells in bone marrow. It is regarded as a multilineage colony-stimulating factor and has similar actions to GM-CSF.

### INTERLEUKIN-4 (IL-4)

IL-4 is involved, together with IL-5 and IL-13, in the differentiation of Th2 lymphocytes from immature Th (helper) lymphocytes. The main physiological function of this class of lymphocytes is the defence against helminthic infections and allergic responses. IL-4 is produced by Th2 lymphocytes and is the major cytokine involved in IgE production after B cell activation and proliferation. IL-4 stimulates expression of certain adhesion molecules (VCAM-1) on endothelial cells to aid rapid transfer of inflammatory cells, especially eosinophils to areas of inflammation. IL-4 inhibits activation of macrophages and the macrophage activating effects of IFN-γ, preventing production of Th1 cytokines, nitric oxide and prostaglandins. IL-10, another Th2 cytokine, shares these effects.

### INTERLEUKIN-5 (IL-5)

IL-5 is a very potent chemotactic agent for eosinophils and acts as a stimulator of B cells. IL-4, IL-5, Th2 lymphocytes and eosinophils are found at sites of allergic reactions and circulating values may be increased in patients prone to allergies.

### INTERLEUKIN-7 (IL-7)

IL-7 is an early growth factor of both B and T lymphocyte cell lines.

### INTERLEUKIN 8 (IL-8)

This is a potent chemotactic agent for neutrophils which together with the inflammatory cytokines have been implicated in ischaemic/reperfusion injury. Pulmonary dysfunction after cardiopulmonary bypass is common and is thought to be caused by neutrophil-mediated endothelial damage and reperfusion injury. IL-8 release correlated significantly with the duration of cardiopulmonary bypass in paediatric patients.[47]

### INTERLEUKIN 9 (IL-9)

IL-9 acts directly on T cell growth, and not merely as a cofactor for the major T cell growth factors such as IL-2, IL-4 and IL-7. It promotes mast cell growth in conjunction with IL-3

### INTERLEUKIN-10 (IL-10)

Most of the immunosuppressive effects of IL-10 result from inhibition of the activity of the antigen presenting cell (APC).[16] IL-10 profoundly suppresses activation of macrophages, inhibiting their ability to secrete cytokines and to act as accessory cells for stimulation of T cell and NK cell function. It has been described as a cytokine synthesis inhibitory factor.

IL-10 down-regulates cell-mediated responses, suppressing the production of $PGE_2$ and pro-inflammatory cytokines, IL-2 and IFN-γ.[16 98] It also enhances release of soluble TNF receptor and inhibits the expression of surface receptor/adhesion molecule ICAM-1.[146]

The Epstein–Barr virus shares similar cellular activities with IL-10 and at least two of the herpes viruses harbour analogues of the IL-10 gene. This may be important in the host–virus relationship. Induction of IL-10 synthesis during infection may be an important strategy by which micro-organisms evade cell-mediated immune destruction and improve the chances of survival. IL-10 also stimulates B cell growth and differentiation.

### INTERLEUKIN-11 (IL-11)

IL-11 has several effects on haematopoietic and non-haematopoietic cell populations. It has synergistic effects with IL-3 and IL-10 on megakaryocytes and pre-B lymphocytes.

### INTERLEUKIN-12 (IL-12)

IL-12 is an important regulator of cell-mediated immune responses because it has multiple effects on T cells and NK cells and is a powerful inducer of IFN-γ production. IL-12 is an important initiator of Th1 cell development acting either directly or indirectly via induction of IFN-γ production. In the presence of IL-4, however, these effects are overcome, favouring the production of Th2 cells. IL-12 is also the most potent stimulator of growth and development of resting, or activated, NK cells and stimulates production of IFN-γ by these cells.

### INTERLEUKIN-13 (IL-13)

This recently discovered cytokine has overlapping physiological properties with IL-4. It has 30% homology with IL-4 and has similar effects on macrophages, monocytes and B cells, but no effect on T cells.[85]

IL-13 can inhibit the production and expression of pro-inflammatory cytokines and, similar to IL-4 and IL-10, is regarded as a potent anti-inflammatory cytokine that suppresses cell-mediated immunity. IL-13 stimulates neutrophils to produce the IL-1 receptor antagonist, IL-1ra, which results in inhibition of the central inflammatory mediator IL-1.[93]

### INTERLEUKIN 14 (IL-14)

IL-14 enhances the proliferation of activated B cells and stimulates immunoglobulin synthesis.[5]

### INTERLEUKIN-15 (IL-15)

IL-15 shares many of the properties of IL-2, including stimulation of T lymphocytes. It is also responsible for *in vitro* generation of alloantigen-specific cytotoxic T cells and non-antigen specific lymphokine activated killer (LAK) cells. It is produced mostly by epithelial cells and monocytes, but is also found in a wide variety of cells.

The IL-15 receptor has the IL-2 receptor beta and gamma chains in its structure, but not the alpha chain.[55]

### INTERLEUKIN-16 (IL-16)

IL-16 has no homology with other known cytokines and was previously known as lymphocyte chemoattractant factor (LCF). It is secreted from CD8+ cells and induces a migratory response in cells expressing the CD4 molecule, namely lymphocytes, monocytes and eosinophils. It may be that IL-16 has the ability to suppress HIV replication in CD8+-depleted monocytes.

### INTERLEUKIN-17 (IL-17)

IL-17 is a protein whose receptors are expressed by a wide variety of cells. It stimulates T cells and acts in a pro-inflammatory manner by activating the transcription protein NF kappa beta, resulting in increased expression of IL-6, IL-8 and ICAM-1 by fibroblasts.

### PLATELET ACTIVATING FACTOR (PAF)

PAF is a family of compounds structurally related to acylglycerol-ether-phosphorylcholine, a membrane phospholipid. It is synthesized after activation of phospholipase $A_2$ and released from platelets, basophils, neutrophils, monocytes and macrophages.[48]

PAF is also released from vascular endothelium by TNF, IL-1 and lipopolysaccharide (LPS) and has been closely linked to the profound shock seen in anaphylaxis and endotoxaemia.[129] A correlation between high concentrations of PAF and profound shock has been shown in patients with acute pancreatitis and severe infections (gram-negative septicaemia, meningitis, malaria). In some animal models, PAF receptor antagonists offer partial protection.[60 72 127]

### INTERFERON-GAMMA (IFN-γ)

IFN-γ is produced by CD4+ and CD8+ T lymphocytes and NK cells and has potent immunoregulatory effects. In common with IFN-α and β, IFN-γ is an inhibitor of viral replication. IFN-γ influences the class of antibody produced by B cells, up-regulates class I and class II MHC antigens, and is an important initiator of the Th1 subset of lymphocytes and subsequent cell-mediated immunity. It increases the efficiency of macrophage-mediated killing of intracellular parasites. IFN-γ counteracts the effects of IL-4 and thus inhibits the activity of Th2 cells.[90]

### INTERFERON-ALPHA (IFN-α), INTERFERON-BETA (IFN-β)

While there is only one gene for IFN-γ and IFN-β, there are 15 functional genes for IFN-α. IFN-α and IFN-β are produced by most cells in response to viral infection. They have potent antiviral activity, but at higher concentrations have antiproliferative activity against both normal and tumour cells. These activities have been exploited therapeutically.

### TRANSFORMING GROWTH FACTOR ALPHA AND BETA (TGF-α AND β)

All cells have receptors for, and respond to, TGF-β. However, there is no structural or functional similarity between the two TGF molecules. Indeed, their roles may be opposed as TGF-α is a growth stimulator while TGF-β is a growth inhibitor (although it can be stimulatory for some cells of mesenchymal origin).

TGF-α is structurally similar to, and shares the same receptor as, epidermal growth factor (EGF), another important member of this large group of cytokine growth factors. EGF stimulates the basal epithelial cell layer of the skin and it can also stimulate bone resorption. The EGF receptor is a transmembrane tyrosine kinase receptor and is over-expressed in various human solid tumours and tumour-derived cell lines, suggesting it is involved in tumour progression.[78] TGF-α has an important role in promoting cell proliferation in various tissues, for example the formation and resorption of bone, and wound healing.

TGF-β is found in the highest concentrations in human platelets and bone, but is produced by many cells. The actions of TGF-β are highly pleiotropic. As a cytokine, TGF-β is important because it antagonizes many lymphocyte responses; it inhibits T cell proliferation, maturation of CTL and macrophage activation. It acts on polymorphonuclear leucocytes and endothelium to counter the effects of pro-inflammatory cytokines. TGF-β can, therefore, be regarded as an anti-cytokine, as it is a negative regulator of immune responses. *Leishmania braziliensis* over-induces TGF-β production, thereby down-regulating the host's immune response and increasing the virulence of this parasite.

Although TGF-β is essentially a growth inhibitor and may be important in preventing uncontrolled proliferation of normal cells in response to mitogenic growth factors, it plays a significant role in tissue repair and regeneration. It can accelerate wound healing by promoting production of the connective tissue components collagen and fibronectin, and is also involved in regulating bone remodelling.

## Cytokine receptors

All known cytokine receptors are transmembrane proteins. The extracellular domain binds the cytokine, thereby detecting the extracellular signal, and the intracellular domain either has enzymatic activity, binds other molecules or uses a second messenger system. Proteins also exist that are structurally similar to cytokine receptors or are able to occupy their binding sites, but are not attached to the cell membrane.

Cytokine receptors have been grouped into seven families determined either by the structure of the extracellular, presenting part of the cytokine receptor, the structure of the intracellular domain of the receptor or by the method of signal transduction. Many cytokines have differing combinations of extracellular domains that may qualify them for more than one family.

### (1) RECEPTOR ONE, THE IMMUNOGLOBULIN RECEPTOR

This group usually displays one or more extracellular immunoglobulin domains. While it principally involves the receptors for IL-1α and β, it also includes some of the sequences of the IL-6R, macrophage colony-stimulating factor (M-CSF) and platelet derived growth factor (PDGF).

There are two distinct types of receptor (type I and type II). In general, type I binds IL-1α better than IL-1β, and type II receptor binds IL-1β more strongly than IL-1α.[38] It has been suggested that the function of the membrane bound type II receptor is to serve as the precursor for a soluble IL-1 binding factor that can be shed under appropriate circumstances to antagonize and modulate IL-1 activity.[128] A naturally occurring IL-1 binding protein has been described that corresponds to the soluble external portion of the type II receptor.[131]

This is the only naturally occurring cytokine receptor antagonist identified to date. It is structurally related to both IL-1α and IL-1β, and binds to the IL-1 receptors without causing signal transduction.

### (2) RECEPTOR TWO

The second receptor to be classified represents the largest group, displaying various combinations of cytokine receptor domains, fibronectin type III (FNIII domain) and, in some cases, immunoglobulin domains.

These receptors bind cytokines that share a four α-helical strand structure, for example IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, G-CSF and GM-CSF. It was known previously as the haematopoietic receptor family.

### (3) RECEPTOR THREE, INTERFERON RECEPTOR (IFNR)

This receptor type includes the type I and type II interferon receptors. One receptor type binds IFN-α and IFN-β and the other receptor binds IFN-γ. Most of the activities attributed to IFN-γ are mediated by IFN-γ proteins, which result from IFN-γ binding to its specific receptor.[58]

### (4) RECEPTOR FOUR, NERVE GROWTH FACTOR RECEPTOR (NGFR)

This fourth group of cytokine receptors, NGFR, includes the two TNF receptors that specifically bind TNF-α and β. The extracellular domains of these two receptors show similarities and can bind with equally high affinity either TNF-α or TNF-β.[34] However, the intracellular domains of the two TNF receptors are unrelated, suggesting they transmit different signals.[10] TNF-α and β use many signal transduction pathways which may explain how only a 5% occupancy of TNF receptors elicits a response.

Several groups have identified soluble TNF-binding proteins in human serum and urine.[105 124 143] Two types of these soluble proteins have been identified; they represent truncated forms of the two TNF receptors. The soluble receptors have a concentration of approximately 1–2 ng $ml^{-1}$ in the serum and urine of healthy subjects. Concentrations vary from individual to individual but are stable over time in an individual.[3]

Increased concentrations of these soluble receptors have been found in a variety of pathological states: endotoxinaemia,[139] meningococcaemia,[54] cerebral malaria,[33] systemic lupus erythematosus,[4] HIV infection[71] and in the plasma and ascites of patients with infections and malignancies.[7 36]

The soluble receptors are probably released from cells by proteolysis but the mechanisms are not well understood.[108] There are reports of a correlation between increased circulating TNF values and soluble receptor concentrations.[108 139] The precise physiological role of the soluble TNF receptor is unknown but these receptors can bind TNF *in vitro*. Thus shedding of soluble receptors scavenges TNF not bound to cell-surface receptors, limiting the effects of TNF and localizing the inflammatory response.

### (5) RECEPTOR FIVE, G PROTEIN-COUPLED SEVEN TRANSMEMBRANE SPANNING FAMILY

The fifth type of cytokine receptor is a seven transmembrane α-helical structure displayed by the receptors of complement 5a, PAF, IL-8 and many related chemokines. This receptor is similar to the structure of the β-adrenergic receptor and rhodopsin. These receptors are coupled to GTP-binding proteins and activate kinases, phosphatases and ion channels.

Members of the chemokine family exhibit 20–50% homology in their predicted amino acid sequence and, depending on slight differences in the positions of these amino acids (a conserved four-cysteine motif), can be divided into an α- and β-subfamily.[91]

### (6) OTHER RECEPTOR TYPES

There is also a group of cytokine receptors that can be classified from their intracellular catalytic domain, tyrosine kinase. On activating this receptor, tyrosine kinase phosphorylates an intracellular transcription protein with further passage of the incoming signal. The seventh cytokine receptor family type is the complement control protein superfamily.

### (7) SOLUBLE RECEPTORS AND SOLUBLE BINDING PROTEINS

The function of soluble receptors is not clear. In some instances, when bound to the ligand, they act as an agonist (sIL-6R) and in other cases as an antagonist (sTNFR). It is important to distinguish between soluble receptors (see above for TNF) and soluble binding proteins that have similar structures to cytokines and inhibit competitively the receptor (IL-1ra). Some of these soluble proteins are non-specific. Alpha-2-macroglobulin acts as a multifunctional binding protein, transporting cytokines to distant sites, but also removing them from the circulation.

In summary, soluble receptors and the soluble binding proteins can function as agonists, antagonists or simply as transport proteins, carrying cytokines to a distant target cell.

## Signal transduction pathways

Signal transduction pathways are activated when a cytokine binds to its membrane-bound receptor. There are several different pathways for signal transduction and most involve protein phosphorylation. Some cytokine receptors have intrinsic enzyme activity (tyrosine kinase activity). Receptors with no intrinsic activity need a mechanism for linking with specific cytoplasmic proteins with enzymatic function. This is undertaken by either stimulatory or inhibitory G (GTP-binding) proteins. These molecules in turn regulate the activity of adenyl cyclase and the production of phosphokinase A, cGMP phosphodiesterase and possibly phospholipases.

### SECOND MESSENGERS SYSTEMS

These systems amplify the initial cytokine signal. Cyclic-AMP–phosphokinase A is one of the best characterized second messenger systems. The activity of this complex can be regulated by phosphokinase C, which is stimulated by cytokines binding to their receptors.[24] Other important second messengers include the phospholipases, enzymes that hydrolyse membrane phospholipids. Phospholipase $A_2$ is the key enzyme in initiating arachidonic acid metabolism and prostaglandin and leukotriene production. Phospholipase C activity results in the production of inositol triphosphate (IP3) and diacylglycerol (DAG). These molecules are important second messengers and play crucial roles in the regulation of intracellular calcium (IP3)[25] and in activating protein kinase C (DAG).[26]

Cytokines stimulating a cell may produce a rapid response or a response which is delayed for several hours or even days. At a cellular level, there is either up-regulation, down-regulation or a switching on or off of gene transcription which alters protein synthesis. One method of rapid transfer of the signal from the plasma membrane to the nucleus is by the use of inactive transcription proteins in the cytoplasm. These proteins are activated by phosphorylation and, when activated, migrate into the nucleus to produce the desired effect.

Signal transduction and gene transcription are currently areas of intense research as they offer possibilities for intervention and modulation of cytokine effects.

## Cytokines and surgery

The cytokine response to surgery involves non-specific inflammation, specific immune responses, haematopoiesis and tissue repair.

### THE ACUTE PHASE RESPONSE

The acute phase response to injury limits tissue damage, isolates and destroys the infective organism, and activates the repair processes that are necessary to return the host to normal function. Usually this response lasts only a few days. However, in cases of chronic stimulation of the inflammatory cascade, continuation of some aspects of the acute phase response may contribute to the underlying tissue damage that accompanies the disease (e.g. rheumatoid arthritis).

The acute phase response consists of:

(i) Alteration of the temperature set point in the hypothalamus and generation of a febrile response mediated through production of $PGE_2$.

(ii) Change in plasma protein composition.

(iii) Increase in the number of granulocytes in peripheral blood, initially as a result of increased release from bone marrow stores and later from increased production.

(iv) IL-1 and IL-6 stimulate adrenocorticotrophic hormone (ACTH) secretion and, consequently, production of cortisol. As corticosteroids inhibit cytokine gene expression, a negative feedback mechanism operates.

Acute phase proteins are synthesized in the liver, which increases in size during this response. These proteins are involved in non-specific/specific immunity as inflammatory mediators, scavengers and protease inhibitors, and in tissue repair. Acute phase proteins include: C reactive protein (CRP), which functions as a non-specific opsonin to augment phagocytosis of bacteria, alpha$_2$ macroglobulin and other anti-proteinases, and fibrinogen.

Over 30 proteins are involved in the acute phase response. Some can be used as useful indicators of the presence and extent of an inflammatory process, for example C-reactive protein (CRP). The rate of increase in concentration of these proteins, and their rate of decline, varies from one acute protein to another. Changes in synthesis are caused by alterations in gene transcription in response to cytokine stimulation.

During the acute phase response plasma concentrations of albumin and transferrin, the iron transport protein, decrease. These are termed the negative acute phase reactants. Most of these changes can be attributed to alterations in the rate of synthesis of these plasma proteins by hepatocytes, while some are caused by increased catabolism.

There are also marked changes in serum concentrations of trace elements. Copper values increase, associated with an increased ceruloplasmin concentration, whereas there is a transient decrease in serum zinc and a persistent decrease in serum iron concentrations. This decline is caused initially by a decrease in serum values of the respective transport proteins (transferrin for iron, and albumin and alpha$_2$ macroglobulin for zinc). This results from increased vascular permeability, which is aggravated after 6 h by reduction in binding of trace element to its protein.[94]

### *Induction of the acute phase response*

The macrophage or monocyte is usually the cell that starts the acute phase response at the site of tissue injury, by releasing a broad spectrum of mediators. These mediators, of which IL-1 and TNF-α are critical, initiate the next series of reactions. These early cytokines act both locally (on stroma cells—fibroblasts and endothelium) and distally, resulting in a secondary phase of cytokine release.[12] Interleukin-6 is released in the second wave of cytokines and is a primary effector in the production of acute phase proteins and accumulation of inflammatory cells.

Circulating IL-6 values increase after all types of major surgery; increased concentrations can be detected as early as 30 min after skin incision and become significantly increased 2–4 h after surgery. The IL-6 response to surgery reflects the extent of tissue damage[29] and is decreased when surgery is undertaken with laparoscopic techniques.[68] Patients with surgical complications have normal initial increases in circulating IL-6, but then develop a large secondary increase followed by a further increase in C-reactive protein.

IL-6, IL-1 and TNF-α have been shown *in vitro* to stimulate the release of ACTH from pituitary cells.[59] Glucocorticoids inhibit IL-6 production in human monocytes but, by up-regulating production of the IL-6 receptor on hepatocytes, increase the acute phase protein response to IL-6.[59]

IL-6, together with TNF-α and IL-1, can inhibit glutamine metabolism if incubated with human fibroblasts for 12 h. Impaired glutamine metabolism results in abnormal cell growth and consequently poor wound healing in critically ill patients.[121] IL-6 activates platelets *in vitro* and enhances agonist-induced platelet aggregation via a mechanism involving cyclo-oxygenase eicosanoid metabolism.[104] This effect may play only a small part in the overall hypercoagulable response to surgery but, in the coronary circulation, changes in platelet reactivity are temporally associated with the development of unstable angina.

It has been suggested that IL-6 may be a more sensitive indicator of the degree of myocardial damage after myocardial infarction than serial creatine kinase (CK) estimations, and an association was found between the size of the IL-6 response and cardiac morbidity.[30] High concentrations of IL-6 impair cardiac function as a result of negative inotropic effects possibly consequent on impaired entry of calcium into myocardial cells.[46] Other cytokines such as TNF-α, IL-2 and PAF also have negative inotropic effects.[53 60 132]

The effects of various anaesthetic techniques on the cytokine and acute phase responses to surgery are receiving increasing attention. Regional anaesthesia had little effect on IL-6 production after pelvic surgery,[88] but it was shown that large doses of alfentanil transiently suppressed IL-6 secretion in a similar surgical model.[28] The cortisol response to surgery is sufficient to down-regulate IL-6 production[67] and large doses of glucocorticoids have been used to decrease the IL-6 and acute phase response to major abdominal surgery.[122] Unfortunately this technique was associated with a high incidence of surgical problems such as wound dehiscence.

## CYTOKINES AND IMMUNOSUPPRESSION

Immunosuppression after major trauma results mainly from T cell dysfunction and is characterized by impaired synthesis of IL-2 and IFN-γ.[43 147] The inability to produce adequate amounts of IL-2 causes incomplete T helper cell proliferation in response to antigen stimulation, and a lack of IFN-γ results in impaired ability of monocyte antigen presentation. These two cytokines are crucial to the development of the Th1 subset of lymphocytes that are responsible for cell-mediated immunity.[99] This down-regulation of IL-2 and IFN-γ appears to be a direct consequence of PGE$_2$ production in the acute phase response.[44] Other immunosuppressants include TGF-β, IL-10 and the naturally occurring antagonists, sTNF-α and IL-1ra. TGF-β induces further production of PGE$_2$ in monocytes and in some environments may produce more cell-associated TNF-α. It also suppresses IL-2- and IL-4-dependent Th development and down-regulates the T cell receptor for IL-1.[84] McBride and colleagues have recently identified significant amounts of circulating IL-10 in patients after cardiopulmonary bypass.[80] IL-10 is produced by Th2 lymphocytes and results in the production of soluble TNF-α and IL-1 receptor antagonist.

In brief, the principal immunological deficit after trauma and major surgery is decreased cell-mediated immunity from an impaired NK cell response and Th1 lymphocyte development. This results in preferential Th2 development, probably as a result of suppression of Th1 development. Recent anaesthetic reports suggest there may be some benefit from infusing cytokines, such as interferon α and β, and IL-2, on NK cell activity.[14 77]

## CYTOKINES AND WOUND HEALING

Cytokines have profound effects on various aspects of granulomatous tissue formation and re-epithelialization, critical problems in burns patients and patients with chronic ulcers.[115] The cytokines primarily involved are TGF-β, PDGF, fibroblast growth factor (FGF), EGF, IL-6 and the proinflammatory cytokines TNF-α, IL-1α and β. The role of TGF-β in wound healing seems contradictory, as it is a potent growth inhibitor for many cell types.

However, TGF-β is usually stimulatory for cells of mesenchymal origin and inhibitory for cells of epidermal origin.[89] There are numerous links between TGF-β and the macrophage, which plays a pivotal role in directing cellular responses required for wound healing. In addition to stimulating its own gene expression, TGF-β can stimulate other growth factors, such as FGF and PDGF. TGF-β is also chemotactic for monocytes and fibroblasts, encouraging their passage into the wound site, and has been shown to increase the strength of wound repair in experimental animals.[92]

PDGF can influence all cells involved in soft tissue repair and is released at wound sites by platelet α granules. Further release of PDGF is continued by activated macrophages and fibroblasts. In conjunction with EGF, other peptides, such as insulin-like growth factors (IGF) help tissue repair. It has also been demonstrated that TNF-α[74] and IL-6[100] promote healing, although over-production can have a deleterious effect.[121] There is evidence that IL-6 values in wound fluid are higher than corresponding serum values,[137] although this may reflect the extent of local tissue damage. Fahey and colleagues suggest that diabetes may obtund this IL-6 response, contributing to delayed wound closure.[42]

In bypass vascular techniques, the main cause of vein graft failure in the early postoperative period is intimal hyperplasia which may be mediated by cytokine growth factors.[63]

## CYTOKINES AND THE EXTRACORPOREAL CIRCULATION

One of the most potent stimuli for leucocyte activation, and therefore cytokine production, is exposure of blood to artificial extracorporeal circuits.[21 22] In clinical practice this concerns patients undergoing renal dialysis and cardiopulmonary bypass (CPB).

There is much conflicting data on cytokines and renal failure with some groups showing an increase in circulating values and other workers finding no change.[107 123] The main stimulus to cytokine production is the dialysis procedure and not the underlying chronic renal failure. Pereira and Dinarello suggested that the variability reported may simply reflect the wide spectrum of cytokine-secreting ability in these patients, as similar variation has been noted in healthy volunteers.[107] Other factors associated with renal failure such as poor nutrition and anaemia can also affect cytokine production. There is more inhibitory activity in plasma from haemodialysis patients than plasma from patients with renal failure and normal subjects. For example, a threefold increase in IL-1ra and soluble TNF-receptor values was found in patients receiving chronic haemodialysis.[37 107]

Cardiac surgery compounds the inflammatory response triggered by the extracorporeal circulation, first by the severity of the surgery and second by the greater damage to the cells in the CPB circuit resulting from high flows and passage through the oxygenator. The cytokine response to cardiac surgery has received considerable attention and was reviewed recently.[135] In brief, the main inflammatory cytokines are IL-6 and IL-8, with only minor increases in IL-1 and TNF. The anti-inflammatory cytokine IL-10 responds rapidly to CPB,[80] and other cytokine antagonists such as IL-1ra increase significantly.[103] Cardiac surgery has a marked suppressant effect on cell-mediated immunity.[62]

Cardiopulmonary bypass results in activation of polymorphonuclear neutrophils and their adhesion to, and chemotaxis through, vascular endothelium. This may be because of expression of CD11b and CD18 on the neutrophil and endothelial cells and expression of the adhesion molecule L-selectin. IL-8 is a neutrophil chemoattractant that induces the cell adhesion molecules CD11 and CD18.[19] Reperfusion injury is a major cause of morbidity after CPB, particularly in myocardium and lung tissue. It seems that the neutrophil, through generation of oxygen-free radicals, upsets the balance between radical-generating and radical-scavenging systems, resulting in reperfusion injury. Detailed discussion of this area falls beyond this article, and is covered well in other reviews.[21 22 83]

## CYTOKINES AND COAGULATION

Cytokines do not directly participate in coagulation reactions, but they may accelerate, or decrease, the rate of specific pathways. Thus, TNF-α and IL-1 activate the procoagulating mechanisms *in vivo*, but do not alter the clotting time.[41] The endothelium has both procoagulant and anticoagulant activities and, in the quiescent state, the latter predominates to favour blood fluidity. Cytokines can alter endothelial cell function; IL-1 increases endothelial procoagulant activity while decreasing expression of thrombomodulin. Fibrinolysis is also inhibited by IL-1, with decreased tissue plasminogen activator (tPA) and enhanced plasminogen activator inhibitor-1.[15] TNF induces tissue factor, suppresses thrombomodulin,[96] depresses endothelial fibrinolytic activity[138] and increases the permeability of the endothelial monolayers.[20]

Abnormalities of the coagulation system are a common finding in inflammatory, immune and neoplastic diseases. Cytokines, forming a key link between host response and the coagulation mechanism, modulate expression of cell surface cofactors, and factors and mediators released from endothelium and monocytes.

## CYTOKINES AND THE VASCULAR ENDOTHELIUM

Features of diseases that involve large blood vessels include dysfunction of the endothelial lining, further stimulating mediators of the inflammatory response, weakening of the artery wall and narrowing of the arterial lumen. Cytokines, and other growth factors, are responsible for the expression of cell adhesion molecules and cell migration into localized areas of vessel injury. Vascular endothelial growth factor (VEGF) stimulates endothelial cells but not smooth muscle production, while platelet derived growth factor (PDGF) has no effect on endothelial cells, but stimulates smooth muscle cell production. Fibroblast growth factor stimulates both types of cell proliferation. These growth factors, sequestered in low concentrations in normal vessels, are released after injury; their action is localized by selected expression on cells and removal by the circulation.[110]

Cell adhesion molecules, notably vascular cell adhesion molecule (VCAM), encourage migration of monocytes and lymphocytes. TNF-α, IL-1 and IFN-α alter vascular permeability by interfering with the endothelial layer.[130] Changes in the contractile state of the arterial smooth muscle, in the absence of endothelium, have been shown with at least four cytokines (EGF, PDGF, TGF-α, IL-1). In addition, the IL-1 induced generation of nitric oxide may explain the hypotension seen after administration of this cytokine.[13]

## Cytokines and the nervous system

### CENTRAL NERVOUS SYSTEM

It had been thought that cytokines, usually associated with the peripheral immune response, would only selectively cross the intact blood–brain barrier. Circulating cytokines are able to stimulate those parts of the CNS outside the blood–brain barrier (circumventricular organs), resulting in a febrile response and release of corticotrophin releasing factor (CRF).[120] Overproduction of some cytokines, such as TNF-α in bacterial meningitis, may lead to tissue injury and breakdown of the blood–brain barrier.[125] It has been demonstrated that while the pro-inflammatory cytokines may not be responsible for this breakdown in integrity of the blood–brain barrier, they are able to cross the disrupted barrier. Saturable transport systems exist for IL-1 and TNF-α, but not for IL-2.

Leucocytes are able to cross the blood–brain barrier as part of an inflammatory response and secrete cytokines. Cellular elements of the CNS such as neurones, glial and endothelial cells are also able to produce cytokines. Glial cells (the microglia is the brain's macrophage) can be activated by IL-1 and TNF-α, produced by T lymphocytes that have migrated into the CNS. These glial cells, after activation, can express either class I or class II types of MHC antigen to either subset of T lymphocyte.

Not only do cytokines have central effects resulting from systemic disease, they also have important roles in acute and chronic neurological diseases. IL-1, at low concentrations, stimulates production of nerve growth factor (NGF) and fibroblast growth factor (FGF), and is neuroprotective. However, in high concentrations, it causes massive exacerbation of the primary insult. IL-1ra markedly limits the extent of damage induced by focal ischaemia or activation of *N*-methyl-D-aspartate (NMDA) receptors in such diverse conditions as stroke, meningitis, excitotoxic damage and heat stroke.[118] Cytokines influence the production and effects of neurotransmitters and are also involved in tissue repair as IL-1 and IL-6 enhance the expression of NGF, and TNF-α initiates gliosis. Cytokines also have behavioural effects, altering sleep patterns and the social response to sickness.

### CYTOKINES AND PAIN

Inflammation is a painful process and recent reviews have emphasized a role for the primary mediators of the cytokine cascade, TNF-α and IL-1β in hyperalgesia.[45 51] Hyperalgesia induced by IL-1β depends partly on induction of bradykinin-1 receptors. It is not surprising, therefore, that pharmacological block of bradykinin and cytokine activity is an area of active pain research.[111] Bicyclic imidazoles, such as tenidap, are under intensive investigation as they have been shown to modify the progress of rheumatoid arthritis by partly interfering with cytokine production.[73]

However, recently attention has been centred on nerve growth factor (NGF). NGF regulates nociception by a direct action on primary afferent fibres, with increased amounts present in inflammation, sunburn and rheumatoid arthritis, and decreased amounts in leprosy, neuropathies and in ageing. NGF modulates the production of substance P and is a key molecule in the understanding of the phenomena of allodynia and hyperalgesia.[6] An anti-NGF preparation has been developed which will help clarify the biological activity of NGF and may increase our understanding of chronic pain.

## Cytokines and pregnancy

There is increasing evidence that cytokines, in addition to the hypothalamic, pituitary and gonadal hormones, play an important part in reproductive function.[119] Several cytokines are involved in pre- and peri-implantation developments, in maternal–fetal interactions and in the initiation of parturition. Enhanced cytokine production may be partly responsible for problems developing in the antenatal period, such as preterm delivery[75] and pregnancy-induced hypertension.[76]

The development of the pre-implantation embryo is more successful and rapid in the uterus than *in vitro*. This suggests that, while the process is autonomous, it is stimulated in the uterine environment. It is likely that epidermal growth factor (EGF), insulin-like growth factors (IGF) and leukaemia inhibitory factor (LIF) are involved in embryo development.[119]

The paternal component of the fetal genome represents a challenge to the maternal immune system. Therefore, modifications to the maternal immune response, both peri-implantation and as the pregnancy develops, occur to avoid rejection of, what is in effect, a partial allograft. Cytokines are important in communication between the developing blastocyst, maternal uterine cells and infiltrating leucocytes before implantation and as the placenta develops.[113]

Cell-mediated immunity is decreased in pregnancy.[49] A relative increase in the Th2 lymphocyte population is found, characterized by enhanced production of IL-4 and IL-10 with increased immunoglobulin production and decreased Th1 activity. IL-2 and IFN-γ (Th1 cytokines) facilitate rejection of the developing allograft and represent one example of how upsetting the balance between Th1 and Th2 cytokines has implications for the clinical course of several autoimmune diseases associated with pregnancy.[49 145] In pre-eclampsia or pregnancy-induced hypertension, increased cell-mediated immunity seems to be partly responsible for an underlying chronic rejection pattern.[76]

Magnesium is used increasingly as an anti-epileptic, sedative and hypotensive agent in the treatment of severe pre-eclampsia. This element is a non-specific, down-regulator of cytokine activity, probably by antagonizing increased intracellular calcium that is an essential signal after stimulation by cytokines.[144] Thus magnesium may work, at least in part, by inhibiting the effects of excessive cytokine activity.

## Cytokines and hypersensitivity

The immune response to allergens is virtually identical to the response to parasites, with large amounts of immunoglobulin E (IgE) produced by B lymphocytes. These B lymphocytes are stimulated by Th cells which recognize antigen displayed on the surface of the antigen presenting cell (APC). These APC stimulate the production of IL-4 which causes the B cells to produce IgE and encourages further differentiation of Th helper cells into Th2 lymphocytes with production of the "allergic" cytokines IL-4, IL-5 and IL-13. In contrast, IFN-γ inhibits this pathway of Th2 cell development and encourages development of Th1 lymphocytes and their specific cytokines IL-2, IFN-γ and TNF-β.[90 116]

Atopic allergy is a genetically determined disorder, characterized by an increased ability of B lymphocytes to produce IgE antibodies to certain forms of ubiquitous allergen, present in low concentration. Essentially, the IgE produced attaches to the $F_C$ fragments of IgE receptors on the surface of mast cells. When the mast cell is next exposed to that antigen, the antigen binds to its IgE receptors, resulting in mast cell degranulation. This degranulation results in the release of vasoactive mediators, chemotactic factors and cytokines that are responsible for the allergic cascade. In addition, eosinophils are also involved, as they invariably accumulate at the sites of allergic inflammation, and the toxic products released contribute significantly to the resulting tissue damage.

Mast cells play not only a central role in immediate allergic responses, but also serve an immunoregulatory function, through production of IL-3, IL-4, IL-5, IL-6 and TNF, and chemokines such as IL-8 (neutrophil chemotaxis).[27] Specific immunotherapy can change the cytokine profiles of the allergic Th2 cells and result in either increased Th1 cells or reduced synthesis of IL-4.[126] IFN-γ stimulates Th1 lymphocyte development at the expense of IL-4 production and hence inhibits Th2 lymphocyte development and causes a decrease in circulating IgE values. In asthma, therapy with an anti-IL-5 compound has resulted in decreased airway responsiveness. IL-4 must be an attractive target for pharmacological intervention because of its role in IgE switching, development of Th2 lymphocytes and induction of eosinophilia.[134] Glucocorticoids are the most potent drugs for controlling airway inflammation, but seem to have their principal effects on inhibiting Th2-type cytokine production (on IL-5 rather than IL-4)[70] and bronchial eosinophilia.[114]

Anaphylactic reactions during anaesthesia occur more commonly in patients with an atopic history. It may be possible to predict those atopic patients at risk of a hypersensitivity response by assessing their "state of reactivity", that is circulating concentrations of IL-4, IL-5 , IL-13 and eosinophil count. Some studies have already attempted to correlate IL-4 with IgE values.[79]

TNF and platelet activating factor (PAF) are important mediators of anaphylaxis. The use of PAF antagonists to obtund the amplification of mediator release in shock has been studied in animal models, where even delayed receptor block had some benefit.[60 72 127]

Cytokines play a central role in IgE synthesis and in the further differentiation and expansion of the various cell lines involved in the allergic response. Atopy is genetically determined but, whether this is a result of increased expression of Th2-type cytokines, decreased expression of Th1-type cytokines or a combination of the two has not been fully determined. Targeting the Th2 lymphocytes and their cytokines seems a promising approach to reduce the chronic inflammatory response of allergy and asthma. In acute and massive mediator release, as occurs in anaphylaxis, specific cytokine receptor antagonism has improved outcome in animal models.

## Cytokines and transplantation

Solid organ and bone marrow allografts represent unique forms of generalized activation of the immune system because of histoincompatibility. Many of the complications of these procedures, including rejection, graft *vs* host disease (GVHD), interstitial pneumonitis, hepatic veno-occlusive disease and microangiopathy can be related to inadequately regulated cytokine production.[64 81]

Patients in the early weeks after bone marrow transplantation are at particular risk of bacterial and fungal infection, the incidence and severity of which are related to the period of neutropaenia. Cytokine growth factors such as granulocyte colony stimulating factor (G-CSF) and granulocyte/macrophage colony stimulating factor (GM-CSF) stimulate myelopoiesis. If these factors are administered during this time, the severity and duration of neutropaenia and therefore the risk of infection, are reduced.

Cytokines play a central role in the rejection response to allograft organ transplantation.[32] The rejection response can be divided into two phases, an afferent and efferent response. The afferent response leads to activation of the recipient's immune system, as a result of recognition of foreign major histocompatibility antigens (class II type MHC or alloantigens) on the surface of donor antigen presenting cells (APC) by the recipient's Th lymphocytes. These cells produce activation antigens which they express on their cell surface. One of these activation antigens has been identified as homologous to the alpha chain of the IL-2 receptor. The Th lymphocytes produce a wide range of cytokines that initiate cellular and humoral rejection mechanisms, and have been identified in the transplanted graft during rejection.[32] IL- 1, IL-2 and IFN-$\gamma$ stimulate the development of Th1 type lymphocytes expressing CD4+ antigen that recognize class II MHC molecule. Occasionally, when mismatch occurs to class I MHC antigens only, CD8+ lymphocytes, the cytotoxic lymphocytes, can act as T helper cells. IFN-$\gamma$ also up-regulates MHC antigen expression on graft tissue, resulting in increased vulnerability of the graft. IL-2 and IFN-$\gamma$ play a central role in the rejection process. The presence of one of these cytokines within the graft may be a sign of early rejection.[31]

The efferent arm of the response occurs as a later event and results in triggering of the humoral and cellular effector mechanisms of the immune response. Immune effector mechanisms involved include delayed-type hypersensitivity reactions, NK cells, LAK cells, antibody-dependent cell-mediated cytotoxicity and complement-dependent antibody-mediated cytotoxicity.

Immunosuppression has been the traditional form of cytokine down-regulation. Non-specific agents, such as glucocorticoids, cyclophosphamide, azathioprine and anti-T-cell antibodies have been used to reduce inflammation in autoimmune diseases and post-transplantation surgery. All of these agents are directed against the T cell compartment and have more general and non-selective immunosuppressive effects. The immunophilin binding drugs, such as cyclosporin and FK506, are more selective and the newer agents give excellent primary immunosuppression and also improve rescue treatments. FK506, a much more potent immunophilin binding drug than cyclosporin, is particularly promising.[52] It inhibits the production of cytotoxic lymphocytes, specifically by blocking the synthesis of IL-2, IL-3, IL-4, GM-CSF, G-CSF, TNF and IFN-$\gamma$. As improved immunosuppression reduces the graft failure from acute rejection, chronic rejection becomes more obvious. Differentiation between acute and chronic rejection is based on time rather than the mechanisms involved.

## Down-regulation of cytokines

Cytokine activity plays a fundamental role in the pathogenesis of many inflammatory diseases. Down-regulation of cytokines, or block of their effects, can occur at various sites. The principles of influencing cytokine production, or immunomodulation, will be discussed only in outline.

### *(i) Immunosuppression*

(a) Glucocorticoids have a direct impact on cell proliferation and inhibit cytokine production.

(b) Azathioprine and cyclophosphamide inhibit cell division and disrupt DNA transcription and RNA translation resulting in decreased cytokine production.

(c) Anti-T-cell antibodies have a direct effect on T lymphocytes and therefore result in decreased T cell function. Naturally occurring autoantibodies against IL-1$\alpha$, IFN-$\alpha$, IFN-$\gamma$, TNF-$\alpha$, nerve growth factor (NGF) and IL-6 have been isolated from normal individuals and patients with acute inflammatory disorders. The significance of these autoantibodies is unknown. Synthesized antibodies (monoclonal antibodies—MAbs) have been developed against cytokines and cytokine receptors. This therapy has also been used with some success against T cell surface markers and leucocyte adhesion molecules.

(d) Immunophilin binding drugs—cyclosporin, FK506. These drugs inhibit immune responses more selectively by forming complexes with cytoplasmic transcription proteins that interfere with calcium-dependent signalling pathways.[50] IL-2 production is inhibited and hence Th1 lymphocyte development blocked.

### *(ii) Blockade of signal transduction*

When TNF binds to its receptor, it activates multiple signal pathways which may be manipulated by specific enzymatic inhibitors. For example, pentoxifylline inhibits TNF production *in vitro*. It is a xanthine derivative, and acts by inhibiting phosphodiesterase resulting in increased intracellular cAMP and decreased cellular mRNA concentrations of TNF. Another important agent is ATP–magnesium chloride (ATP–$MgCl_2$). Magnesium deficiency increases circulating IL-1, IL-6 and TNF-$\alpha$ in rodents.[144] Calcium channel antagonists may also change the cytokine response. For example, diltiazem enhanced production of cytokines and maintained immune function after haemorrhage.[82]

### *(iii) Cytokine receptors and receptor antagonists*

Cytokine receptors can be targeted in several different ways:

(a) antibodies against receptor;

(b) soluble proteins binding competitively to membrane-bound receptor;

(c) development of amino acid substitution in cytokines.

The two most studied naturally occurring specific inhibitors of cytokines are IL-receptor antagonist and soluble TNF receptors. Biological responses to IL-1 can be induced by occupancy of as few as 5% of IL-1 receptors, and *in vivo* up to 100-fold excess of IL-1ra is required to inhibit 50% of IL-1 induced responses.[40] This indicates the presence of a large number of IL-1 receptors on cells compared with the number that need to be occupied to trigger a biological response.[40] As the pattern of production and regulation for IL-1 and IL-1ra is different, the exact relationship between the two cytokines remains to be established.[8]

Soluble TNF receptors represent the cleaved extracellular domains of the TNF receptors, type I and type II. Their functions are complex; they may serve as TNF inhibitors, TNF reservoirs or, in some situations, even augment TNF effects by stabilizing its tertiary structure and prolonging its action.[2]

### *(iv) Alpha$_2$-macroglobulin*

This is a non-specific, multi-functional binding protein that serves as a proteinase inhibitor, a carrier protein and a cytokine modulator. Other examples of naturally occurring non-specific inhibitors of cytokines include lipoproteins and lipids.[38]

## CYTOKINE DOWN-REGULATION OF IMMUNE FUNCTION

There are several cytokines, TGF-β, IL-10 and IL-4, whose normal function is to inhibit further cytokine development.

### *(i) Transforming growth factor B (TGF-β)*

TGF-β promotes extracellular matrix formation and stimulates some mesenchymal cells, but also inhibits the growth of a variety of normal and transformed cells, including B cell maturation and release, NK cell activity and release of cytokines by T cells.

### *(ii) IL-10*

Interleukin-10 is produced by a selected subset of Th2 cells, macrophages and B lymphocytes with the other Th2 cytokines, IL-4 and IL-5.[48] IL-10 also inhibits antigen presentation to Th1 cells, up-regulation of the MHC class II antigen and production of TNF-α, IL-1 α, IL-1 β, IL-6 and IL-8.[35] However, IL-10 up-regulates B cell proliferation, differentiation and immunoglobin synthesis. It suppresses the production of Th1 cytokines (IL-2, IL-3, IFN-γ, TNF-β and GM-CSF).

### *(iii) IL-4*

IL-4 induces production of IL-10, a cytokine inhibitory factor, as detailed above. It also increases the production of CD8+ cytotoxic cells and decreases the number of CD4+ cells, NK cells, IL-2 activated killer cells and down-regulates IFN-γ.[106]

## Summary

The scope of cytokine biology is fascinating with widespread applications anticipated in many areas of medical science. We have emphasized the fundamental roles that cytokines play in the control of normal immunological functions, defence mechanisms and normal cell growth, and how major surgery and trauma can affect these processes. It remains to be determined if morbidity and mortality may be improved after major illness and surgery by altering cytokine production and function.

SHORT COMMUNICATIONS

# The laryngeal mask airway and the tracheal route for drug administration

R. ALEXANDER, H. SWALES, A. PICKFORD AND G. B SMITH

## Summary

We undertook a study to observe if a preformed curved plastic cannula, the Trachojet, could be passed blindly down a laryngeal mask airway into the trachea in 100 anaesthetized patients. Using air aspiration and a fibreoptic scope to confirm placement of the cannula, it passed into the trachea in only 27% of patients. The air aspiration technique used for detecting tracheal cannulation was 100% successful when the cannula was inserted fully. We conclude that it may not be possible to gain access to the trachea with a Trachojet for drug administration if a laryngeal mask airway is used to maintain the patient's airway. (*Br. J. Anaesth.* 1997; **78**: 220–221)

**Key words**
Equipment, masks anaesthesia. Equipment, cannulae.

The European Resuscitation Council (ERC) recommends that the tracheal route should be used for cardiac drug administration during cardiopulmonary resuscitation (CPR) if an i.v. route cannot be established. However, if a laryngeal mask airway (LMA) is used to maintain a patient's airway, tracheal access is not guaranteed, as the LMA does not pass through the vocal cords.

The Trachojet (Evans Medical, Dunstable, Bedfordshire, UK) is a plastic, anatomically curved cannula manufactured for tracheal and endobronchial administration of drugs. It has a Luer lock connector at its proximal end for attachment of a syringe and a flange to prevent its loss into the tracheal tube. There are multiple holes to produce a spray of the injectate at the distal end with guide markings at 23, 25 and 27 cm. When inserted fully into the lumen of the LMA, the Trachojet protrudes the grille of the LMA by at least 3 cm more than the longest distance previously measured between the grille and the vocal chords.[1]

The aim of this study was to investigate if the Trachojet would enter the trachea in anaesthetized patients if passed blindly into the stem of the LMA.

## Methods and results

Local hospital Ethics Committee approval was granted and informed written consent obtained from 100 patients, ASA I or II, undergoing elective surgery. Exclusion criteria were any patient not scheduled to have an LMA inserted as part of the anaesthetic technique, those with abnormal laryngeal or tracheal anatomy, or those aged less than 18 yr.

Monitoring in the anaesthetic room included ECG, pulse oximetry and automated non-invasive arterial pressure measurement. Anaesthesia was induced with propofol 2 mg $kg^{-1}$ and fentanyl 1 $\mu g$ $kg^{-1}$ i.v. When anaesthesia was of sufficient depth to obtund laryngeal reflexes, an LMA was inserted using the technique described by the manufacturer (Intavent Ltd, Tidmarsh, Berkshire, UK) with the patient's head extended on the neck. If the LMA could not be inserted on the first attempt then the procedure was repeated, with increments of propofol as necessary. Insertion was considered successful if the LMA was inserted fully and the patient's lungs could be inflated easily. Insertion was considered difficult if it took more than two attempts. The patient was then allowed to breathe spontaneously and anaesthesia was deepened with 2.5–3% isoflurane in oxygen. After at least 5 min of preoxygenation and when the patient's vital signs had stabilized, fresh gas flow was disconnected. A Trachojet was then passed down the lumen of the LMA as far as possible with the patient's head still extended. Tracheal placement was noted by aspiration of air, as described by Wee[2], with a syringe attached to the Luer lock of the Trachojet. The position of the Trachojet was then confirmed visually using a fibreoptic scope passed down the lumen of the LMA alongside the cannula. The two instruments were then removed from the LMA and the patient reconnected to the fresh gas flow. Nitrous oxide was added and the concentration of volatile agent decreased accordingly and surgery proceeded. Only one insertion of the Trachojet was attempted in each patient. No patient showed signs of inadequate depth of anaesthesia.

Data recorded included patient age and weight, size of LMA used and if insertion of the LMA or

*Table 1* Number of patients requiring a size 3 or 4 LMA, number of easy and difficult insertions of both the LMA and Trachojet, and the corresponding number of successful tracheal cannulations

| | Tracheal placement | Extra-tracheal placement |
|---|---|---|
| Size 3 LMA ($n$=76) | 22 | 54 |
| Size 4 LMA ($n$=24) | 5 | 19 |
| Easy insertion of LMA ($n$=85) | 25 | 60 |
| Difficult insertion of LMA ($n$=15) | 2 | 13 |
| Easy insertion of Trachojet ($n$=61) | 17 | 44 |
| Difficult insertion of Trachojet ($n$=39) | 10 | 29 |

Trachojet was easy or difficult (more than two attempts). The final position of the Trachojet was recorded as either having entered the trachea or not. Statistical analysis was performed with chi-square tables (StatView 1.04, Apple Macintosh) and a value of $P<0.05$ was considered statistically significant.

We studied 100 patients, with no exclusions. Mean age of the population was 47 (range 22–83) yr and mean weight 68 (47–87) kg. The Trachojet passed into the trachea in only 27 patients. In 12 patients the cannula caught on the lip on the posterior wall of the aperture behind the grill. In the remaining 61 patients it passed into the oesophagus and the piriform fossae in 43 and 18 patients, respectively.

The number of patients with a size 3 or 4 LMA is shown in table 1. There was no significant difference in the success rate of tracheal cannulation in relation to the size of LMA used or if the LMA or Trachojet were inserted with ease or difficulty ($P$=0.07 and $P$=0.1, respectively) (table 1). The aspiration test was 100% accurate in determining tracheal and oesophageal placement of the Trachojet when inserted fully down the stem of the LMA. The test gave a false positive result in the 12 patients in whom the Trachojet impinged on the grille. However, as the cannula could not be inserted fully it was appreciated in each case that the Trachojet had not entered the trachea before confirmation with the fibreoptic scope.

## Comment

Securing a patent airway, supplying oxygen and protecting the lungs from aspirated stomach contents are vital aspects of CPR. Some resuscitation drugs may be administered into the lungs via the trachea and this may be invaluable when i.v. cannulation cannot be obtained. Usually these aims are achieved by tracheal intubation but, occasionally, this may not be possible. Indeed in a multicentre study of 164 patients in which nurses used the LMA as an initial method of airway maintenance and ventilation at cardiac arrest, the trachea could not be intubated in 11 (7%) patients and it was necessary to reinsert the LMA.[3] Clearly, if a vein had not been cannulated in these patients, cardiac drugs could not be administered via the tracheal route. In order for resuscitation drugs to reach the trachea it would be necessary for them to be delivered via a cannula placed within the lumen of the LMA.

Previous investigations have demonstrated variable success in the placement of similar devices into the LMA. Alison and McCrory reported a success rate of 84% in passing a gum elastic bougie blindly down the LMA into the trachea as part of a difficult intubation technique.[4] Successful tracheal placement of an unspecified airway exchange catheter via the LMA has also been reported in a patient who's trachea was difficult to intubate.[5] However, Brimacombe and Berry reported a success rate of only 30% in placing a Cook airway exchange catheter in the trachea of 20 patients when passed blindly down an LMA.[6] The high failure rate was attributable to the catheter being too rigid and having insufficient curvature so that the catheter emerged from the posterior aspect of the aperture thereby favouring oesophageal placement.

The Trachojet is anatomically curved and when it is inserted into the stem of an LMA *in vitro* it emerges on the anterior aspect of the aperture, thereby favouring tracheal placement. However, our success rate *in vivo* was only 27% and was similar to the findings of Brimacombe and Berry.[6] In 12 of our patients the cannula impinged on the posterior lip of the aperture and could not be passed further. *In vitro* it was clear that, if the stem of the LMA was flexed to simulate its passage between the tongue and the posterior pharyngeal wall, then the Trachojet emerged on the posterior aspect of the aperture, so favouring oesophageal placement, despite its curve. All patients had the head extended on the neck when the cannula was inserted to optimize the direction of passage of the Trachojet and coincidentally reducing the flexion of the stem of the LMA. When viewing the final placement of the cannula it was noted when the fibreoptic scope reached the grille of the LMA that the oesophagus was visible in only one of 100 patients and that in this case the cannula had entered the trachea.

We conclude that further modification to the LMA may be necessary before it can be used in conjunction with cannulae such as the Trachojet for administration of drugs during cardiopulmonary resuscitation.

## Acknowledgements

We thank Evans Medical for the supply of Trachojets and Professor J Norman for his help with the statistical analysis

# Low-dose mivacurium supplementation of prilocaine i.v. regional anaesthesia

J. M. TORRANCE, B. M. F. LEWER AND D. C. GALLETLY

**Summary**

We have compared in two groups of five healthy volunteers, the motor effect of prilocaine i.v. regional anaesthesia of the forearm with and without addition of mivacurium 0.6 mg. Although addition of mivacurium might, theoretically, provide the benefit of increased neuromuscular block with rapid plasma cholinesterase degradation in the isolated limb, we observed prolonged forearm weakness in the mivacurium group using tests of grip strength (median recovery to 90% of control, 80 min (range 60 min to >8 h) *vs* control median recovery to 90% of 16 (8–24) min) and bead transfer (median recovery to 90% of control 36 (24–48) min *vs* control median recovery to 90% of 12 (8–16) min). This weakness was considerably in excess of that predicted by rapid systemic degradation of mivacurium. The mivacurium group experienced symptoms of local anaesthetic toxicity which did not occur in the control group and which could not be replicated by administration of mivacurium alone. (*Br. J. Anaesth.* 1997; **78**: 222–223).

**Key words**
Neuromuscular block, mivacurium. Anaesthetic techniques, regional. Anaethetics local, prilocaine.

Forearm fractures are commonly reduced as outpatient procedures using i.v. regional anaesthesia (IVRA). These fractures often cause muscle spasm which increases bone impaction and the traction that is required for fracture reduction; IVRA with local anaesthetic alone provides poor neuromuscular block. Paralysing the arm by adding a small dose of neuromuscular blocking agent to the local anaesthetic has been shown to facilitate fracture reduction, decrease the pain experienced by the patient both during and after the procedure, and may obviate the need for hospital admission and general anaesthesia in some muscular young patients.[1–3]

Many different neuromuscular blocking agents have been used in small doses with few reported side effects other than transient diplopia and difficulty with accommodation. These include tubocurarine 1 mg, gallamine 10 mg, atracurium 2–5 mg, suxamethonium 4 mg and decamethonium 0.2 mg.[2 3] Ideally, to limit the systemic effects of the neuromuscular blocking agent on deflation of the cuff, the blocker should have a shorter duration of action than the duration of cuff inflation. Atracurium undergoes Hoffmann degradation under mild alkaline conditions and should decay spontaneously in the isolated limb. However, most studies have demonstrated that atracurium produces prolonged paralysis when used to supplement IVRA, which may in part be caused by decreased Hoffman degradation related to the acidic environment of the ischaemic limb.[1 2 4]

Mivacurium is hydrolysed by plasma cholinesterase and may therefore be degraded in the isolated limb provided there is sufficient plasma cholinesterase activity after exsanguination of the limb which must inevitably be incomplete. In this study mivacurium was added to IVRA with 0.5% prilocaine and its effect on the development of motor block and on the return of motor function was investigated. Earlier studies with suxamethonium, which is also degraded by plasma cholinesterase, have yielded conflicting results.[3] If degraded in the isolated arm, mivacurium would confer the benefits of ease of reduction and decreased pain with a low risk of systemic effects.

## Methods and results

We studied 10 healthy, fasted and consenting volunteers in a double-blind, controlled study that was approved by the Wellington Ethics Committee. I.v. cannulae (22-gauge) were sited in the dorsum of both hands and the IVRA was performed on the non-dominant arm. The limb was elevated for 1 min and an upper arm tourniquet inflated to 300 mm Hg. Volunteers were allocated randomly to one of two groups of five subjects (age and weights were not significantly different, one female in each group) to receive either 0.5% prilocaine 40 ml (control) or 0.5% prilocaine 40 ml with mivacurium 0.6 mg (mivacurium group). The tourniquet remained inflated for 20 min after injection of local anaesthetic.

Immediately before drug injection, baseline

J. M. TORRANCE, BSC (HONS), MB, BCH, DA (UK), B. M. F. LEWER, MB, BCH, FANZCA, FFA (SA), D. C. GALLETLY, MB, CHB, FANZCA, FRCA, Section of Anaesthesia, Wellington School of Medicine, Private Bag, Wellington, New Zealand. Accepted for publication: October 30, 1996.

neuromuscular strength and co-ordination were assessed and these were repeated every 4 min until the test variables had returned to baseline or 2 h had elapsed. Crude grip strength was measured by recording the maximum pressure generated by asking the subject to maximally compress a rubber bulb connected to a pressure gauge. The number of beads transferred from one container to another in 15 s with a pair of forceps was used as a test of fine motor skills. Complete neuromuscular block was defined as complete loss of all voluntary movement in the fingers, hand and arm below the cuff.

Complete forearm muscle paralysis occurred in none of the controls and in only two subjects in the mivacurium group and then only after 18 min of limb ischaemia. Muscle strength decreased rapidly in both groups while bead transferral decreased more rapidly in the mivacurium group.

Time to recovery of grip strength to baseline, after deflation of the tourniquet, was significantly more rapid in the control group than in the mivacurium supplemented group (Mann–Whitney *U* test, $P<0.004$). Median time from tourniquet deflation to recovery to 90% of baseline grip strength in the control group was 16 (range 8–24) min. Recovery in the mivacurium group was prolonged (median 80 min (range 60 min to >8 h)). Three of the volunteers who had received mivacurium had not achieved baseline strength within the study duration of 2 h and in one subject grip strength had not returned to baseline 8 h later. Time to baseline recovery of fine motor skills for the bead transfer test was significantly slower in the mivacurium group (Mann–Whitney *U* test $P<0.004$). Median time for return to 90% of baseline of bead transfer was 12 (8–16) min in the control group and 36 (24–48) min in the mivacurium group. Although not specifically tested, there appeared to be no qualitative difference in return of sensation between the two groups.

All volunteers who had received mivacurium in the prilocaine ischaemic arm block spontaneously volunteered symptoms of light headedness, dizziness, perioral paraesthesia, tinnitus, diplopia, blurred vision, altered hearing or slurred speech. These symptoms began 1–2 min after deflation of the tourniquet and lasted for 5–15 min. No adverse effects were volunteered by subjects in the control group. When mivacurium 0.6 mg was injected i.v. into one of the volunteers who had experienced these adverse effects, none of these symptoms of presumed local anaesthetic toxicity was experienced, apart from diplopia which lasted for 10 min.

Two of the five volunteers who received mivacurium developed urticarial weals on the arm several minutes after cuff deflation. One had experienced some pruritus while the cuff was inflated. Neither had a history of atopy.

## Comment

Our results demonstrated that supplementation of prilocaine IVRA with mivacurium resulted in prolonged muscle weakness on cuff deflation, as has been reported with other non-depolarizing neuromuscular blocking agents. This slow recovery suggests that mivacurium is not broken down in the ischaemic limb and that recovery of neuromuscular function is not dependent on plasma concentration, which would be expected to decrease rapidly with washout and dilution on reperfusion of the limb to concentrations too small to affect recovery of the block.[5] Recovery from a drug effect is dependent on plasma concentration only if the plasma concentration decreases slowly; however, if the plasma concentration decreases rapidly, then recovery of neuromuscular function is related to the transfer of mivacurium from the biophase to the plasma. Feldman, Wu and England[5] postulated the presence of binding sites that form a reservoir of drug close to the receptor. Recovery from non-depolarizing neuromuscular blocking agents would therefore reflect not only binding to the acetylcholine receptor but also the kinetics of binding to the reservoir binding sites.

All volunteers who received the combination of mivacurium and prilocaine displayed symptoms of local anaesthetic toxicity that were absent in the control volunteers. Apart from diplopia, none of the symptoms was reproduced when mivacurium 0.6 mg was given i.v. to a volunteer who had demonstrated these side effects. Despite the small numbers, these symptoms were a consistent finding and occurred with a far greater incidence than the 1–2% incidence of minor adverse reactions reported in the literature for IVRA.[6] This interaction has not been reported in previous studies and may warrant specific investigation.

Development of urticarial weals would suggest an increase in vascular permeability. The fact that normal intravascular hydrostatic pressure only occurs on deflation of the tourniquet would explain the delayed development of the urticarial weals.

In summary, mivacurium increases the degree of paralysis of the forearm when added to IVRA, although as with other blocking agents, the neuromuscular blocking effect has a duration well in excess of that of tourniquet inflation.

CASE REPORT

# Anaphylaxis associated with, but not caused by, extradural bupivacaine

S. M. RAE, M. K. MILNE AND J. A. W. WILDSMITH

## Summary

Identifying anaphylaxis and determining its cause during anaesthesia can be very difficult. We describe a patient who suffered a life-threatening reaction which was diagnosed originally as being caused by bupivacaine. Subsequent investigation and enquiry showed that this was not so and suggested latex as the likely true cause. (*Br. J. Anaesth.* 1997; **78**: 224–226)

**Key words**
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Anaesthetics local, bupivacaine. Complications, anaphylaxis.

Allergy to amide local anaesthetics is rare, but has been reported.[1] More common is the patient who is labelled as being allergic to these drugs when this is not the case. Given the significance of the diagnosis, and the problems it produces for dental treatment in particular, it is essential to confirm the true situation in such patients. The following case report illustrates these issues.

## Case report

A 33-yr-old woman with a history of immune complex disease, but no evidence of vasculitis, presented for elective Caesarean section. She was not receiving any medication and had no drug allergies. She had previously undergone an emergency Caesarean section under uneventful extradural block with bupivacaine and was happy to receive the same anaesthetic again.

Approximately 1 h before the procedure she received 30 ml of sodium citrate 0.3 mol litre$^{-1}$ and ranitidine 300 mg, but no sedative medication. On arrival in the anaesthetic room, her systolic arterial pressure was 120 mm Hg and heart rate 90 beat min$^{-1}$. An extradural catheter was inserted at the fourth lumbar interspace and a total of 18 ml of 0.5% bupivacaine was injected in increments. At 25 min a bilateral block to T2 had developed, but surgery was delayed by an emergency elsewhere. During the interval she was kept in the left lateral position, arterial pressure decreasing only to 105 mm Hg and heart rate remaining unchanged. At 40 min, preparations for surgery began with urethral catheterization in the wedged, supine position. Immediately after catheterization her arterial pressure decreased to 70 mm Hg systolic, but responded initially to increments of i.v. ephedrine. However, she then became nauseated, vomited and developed persistent hypotension. Surgery was started and she required 2200 ml of i.v. crystalloid and increments of ephedrine and metaraminol to maintain systolic pressure at 100 mm Hg before delivery. The baby was born in good condition (Apgar score 9 at 1 and 5 min) 13 min after skin incision.

After delivery the patient became acutely breathless and clinically cyanosed, and arterial pressure could not be recorded, although peripheral pulses were palpable. She lost consciousness and her trachea was intubated after administration of suxamethonium 100 mg. I.v. frusemide and increments of adrenaline were administered for suspected pulmonary oedema and left ventricular failure. She remained hypotensive (systolic arterial pressure 65 mm Hg) and tachycardic (150 beat min$^{-1}$) and at this point developed a generalized erythematous rash. During the procedure she lost an estimated 500 ml of blood and received Syntocinon 10 u. At the end of the operation she was transferred to the intensive therapy unit where artificial ventilation was continued. Arterial pressure responded to 2800 ml of colloid and 1 u. of red cell concentrate. She was noted to have marked peripheral oedema. Coagulation screens remained normal throughout and there was no evidence of amniotic fluid in the maternal blood samples. Her trachea was extubated 5 h after admission to the unit and the following day she was transferred to the postnatal ward where her subsequent recovery was uneventful.

An anaphylactic drug reaction was considered as the explanation for this event and advice was sought from the National Adverse Anaesthetic Reactions Advisory Service, Sheffield. Blood samples for radioallergosorbent tests were obtained and that for suxamethonium was negative. No test was available for bupivacaine, but a diagnosis of a specific reaction to bupivacaine was thought likely and the patient was advised to avoid future exposure to bupivacaine. It

---

S. M. RAE, BSC(MED SCI) HONS, FRCA, M. K. MILNE, MB, CHB, FRCA, J. A. W. WILDSMITH, MD, FRCA, University Department of Anaesthesia, Ninewells Hospital and Medical School, Dundee DD1 9SY. Accepted for publication: October 30, 1996.

was considered that intradermal testing would not be helpful.

Subsequent to this event, dental work was carried out uneventfully (as it had been previously) using 3% prilocaine with octopressin, but then local infiltration for further treatment was performed using 2% lignocaine with adrenaline 1 in 80 000. After this the patient developed a severe headache which was probably an adrenaline reaction, but she was concerned that she was experiencing allergy to yet another local anaesthetic drug and was referred, some 7 yr after the original event, to the anaesthetic department for further investigation.

A review of her medical and dental notes was undertaken and revealed that she was known to the dentists to be allergic to latex, but this information was not in the medical notes. Given this fact, and the temporal relationship of the original collapse to insertion of the bladder catheter, it was felt that the latter was the more likely cause of the acute event. Investigations revealed that latex catheters were in routine use in the labour unit at the time of the reaction. Challenge testing with local anaesthetic drugs was agreed with the patient to eliminate them as the cause of her problem and so that further dental treatment could proceed. With appropriate safeguards a series of intradermal injections was performed. At 10-min intervals 0.1-ml increments of normal saline, 0.01% lignocaine, 0.1% lignocaine, 0.05% bupivacaine, 0.5% bupivacaine and 0.5% prilocaine with methyl paraben were injected. The test drugs produced no more erythema than the saline control, and therefore 1% lignocaine 1 ml was injected s.c. before, finally, 0.5% bupivacaine 1 ml was given i.v. There was no reaction.

## Discussion

An adverse reaction to a local anaesthetic agent may result from the systemic effects of the drug or the nerve block it produces, an allergic reaction to some component of the solution, a vasovagal reaction to the situation, or may be temporally, but not causally, related to administration of local anaesthetic. This patient was stable for 40 min before developing hypotension and subsequent loss of consciousness. Systemic toxicity, inadvertent spinal anaesthesia and allergy to some component of the local anaesthetic solution are unlikely as all would be expected to present within minutes of drug administration. The patient did not become bradycardic and this makes a vasovagal event unlikely also. Extensive sympathetic block could produce some of the features seen, but would not explain the generalized erythematous rash or the later oedema, and arterial pressure was stable until preparation for surgery. Turning her to the supine wedged position for catheterization might have compromised arterial pressure, but would not have produced the other features. Hypotension, respiratory difficulty and rash are compatible with an immunological reaction and we propose that this was in response to either the antiseptic (Hibitane) or the urethral catheter, with ranitidine therapy and extensive sympathetic block compounding the situation. Syntocinon might cause such a reaction, but none was administered until well after it had commenced. Reports of allergy to skin antiseptics are beginning to appear[2] and latex allergy is well documented.[3 4] Given that she is now known to be allergic to latex this seems the most likely cause of the reaction. More recently she was accidentally exposed to latex and developed skin oedema and swelling at the point of contact. A further deterioration in her condition occurred after delivery and Syntocinon could have contributed to this.

In this patient, anaphylaxis was diagnosed with the onset of the rash. The diagnosis is easy when cardiovascular collapse is immediately associated with bronchospasm and cutaneous signs, but the latter only appear in 65% of cases.[5] The differential diagnosis of these symptoms in the absence of cutaneous manifestations is difficult and includes not only anaphylaxis, but also drug overdose, haemorrhage, air emboli, bronchial intubation, aspiration, etc. Fortunately, and despite difficulties in diagnosis, treatment is often the same: adequate oxygenation, with sympathomimetic drugs and i.v. fluids. If anaphylaxis is thought possible, potential antigens must be sought and exposure terminated. This patient eventually responded to treatment, but recovery took several hours, probably because the urinary catheter was not suspected as the cause and was left *in situ*. There are no investigations that can be performed during a reaction that aid diagnosis or acute management, but estimation of serum tryptase concentration approximately 1 h after onset is helpful in the subsequent investigation.[6 7] This test was not available at the time of our patient's reaction. After the patient's recovery a detailed history of the event, and examination of all past notes, should be undertaken in an attempt to ascertain the cause of the reaction. If our patient's latex allergy had been documented in her medical notes she would not have been exposed to latex and one of the drugs she received would not have been blamed for the reaction.

If the history suggests anaphylaxis rather than anaesthetic misadventure, or serum tryptase concentration is increased, skin prick testing, as recommended by the recently published Association of Anaesthetists' Guidelines (*Anaphylactic Reactions Associated with Anaesthesia*) may be undertaken to try and establish the cause of the reaction. These guidelines recommend that all reagents administered around the time of the reaction should be used in testing, in addition to a range of agents that may be used in the future. Our patient was challenge tested with local anaesthetic agents because of her concern about continued use. There was no real benefit for her in being tested for latex or Syntocinon, which she had refused in any case. There is ample clinical evidence from her dental attendances that she reacts to latex with skin swelling and oedema, and testing would have exposed her to a small, but real risk of life-threatening anaphylaxis. She intends having no more children and so will not be exposed again to Syntocinon.

Intravascular injection is not recommended in routine testing because a severe response is likely if the true antigen is injected. In this patient's case intravascular injection with bupivacaine was performed because she expressed a wish to be certain that she was not allergic to this drug. It was felt that this was a safe procedure because there had been no reaction to intradermal bupivacaine and the history clearly suggested latex as the true cause of the original problem, although Syntocinon cannot be totally excluded from a contributory role. The testing did prove definitively that the patient was not allergic to local anaesthetic drugs, and the case illustrates clearly the need to consider all aetiological possibilities when anaphylaxis occurs during anaesthesia.

## Flow cytometry

Sir,—With regard to the article by Heine and colleagues,[1] we believe that several points require clarification.

The authors claim that the technique using 123-dihydrorhodamine is more specific than the more well known chemiluminescence technique for measuring neutrophil respiratory burst. Such claims remain unsubstantiated. Readers may infer from the article that the chemiluminescence method is of less value than the authors' technique. The chemiluminescence technique is not non-specific. It is based on the production of light by activated cells in the presence of enhancers such as luminol or lucigenin. The production of light is dependent on the presence of superoxide anion and hypochlorous acid (produced from superoxide). Singlet oxygen does not produce light in this system.[2]

The only apparent benefit of the dihydrorhodamine technique is its flow cytometry base, allowing the study of a single cell population within a mixed cell environment. However, in the study by Heine and colleagues[1] such benefit is negated by separation of individual cell populations. The cell separation technique as presented is unclear. The layering of whole blood onto Ficoll-Hypaque density medium would result in a mononuclear cell layer with all granulocytes sedimenting with erythrocytes. However, the light scatter diagrams show mixed cell populations comprising monocytes, lymphocytes and granulocytes. It is difficult to see how the data relate to the methodology given or the need for cell separation in the first place.

The propofol carrier, 10% Intralipid, inhibited respiratory burst of granulocytes in an identical manner to that of propofol.[1] However, any effect of Intralipid on either light scatter or light quenching in the flow cytometry system is not discussed. In addition, cited literature has been misquoted. Intralipid was not shown to suppress T cell-mediated immunity as stated.[3] Other studies have confirmed this finding.[4] The effects of lipid emulsions on cell function are dependent on cell type and whether or not the study involves isolated cells *in vitro* or cells after *in vivo* lipid exposure.[3–6] In addition, the antioxidant effects of propofol have not been discussed.

Finally, the use of isotonic saline to dissolve thiopentone and methohexitone preparations inevitably resulted in hypertonic solutions. This may be inappropriate because hypertonic solutions induce a stress response, affect cell function and may also affect respiratory burst activity.[7 8] Pre-exposure of cells to anaesthetic agents before stimulation with PMA[1] implies that the results may represent the effect of the drugs on protein kinase C rather than on NADPH oxidase directly. This factor is not discussed. Protein kinase C is also affected by hypertonic solutions.[9]

Sir,—We thank Drs Galley and Webster for their interest, however, we are not in accordance with the majority of their comments concerning our article.[1]

They stated that the only apparent benefit of the dihydrorhodamine technique appears to be its flow cytometry base. With regard to our study design, the most important difference between the applied technique compared with chemiluminescence is that the dihydrorodamine technique involves actual measurement of the activity of the respiratory burst oxidase. This enzyme is responsible for intracellular superoxide anion production.[2] In our study respiratory burst activity of only viable neutrophils was analysed in a whole blood system. As the number of analysed events in flow cytometry is practically unlimited, data with low variation coefficients are produced and sensitivity can be increased. Sedimentation at 1 g and 22 °C was used as a reduction of erythrocytes in the whole blood samples, as shown in the light scatter diagrams.[1] Thus no centrifugation or erythrocyte lysis was required and preactivation or impairment of neutrophil function was avoided. This does not imply that chemiluminescence itself is a less valuable method and we did not state so in our article.

Furthermore, Drs Galley and Webster claim that the effect of Intralipid on either light scatter or light quenching in the flow cytometry system had not been discussed in our article. We described in detail the effects of 10-fold anaesthetic doses of propofol and Intralipid on side scatter signals (SSC) in the results and also in figure 5. Figure 5 was given as an example of the decrease in SSC signals of neutrophils which were incubated with the 10-fold anaesthetic doses of propofol. We discussed further if the changes in the cell membrane structure induced by lipid solutions may provide an explanation for the observed decrease in the SSC signals.

We apologize for citing the article of Monson and colleagues who reported stimulation of T cells by lipid solutions under impairment of T cell-mediated immunity.[3]

Suppression of intracellular enzyme respiratory burst oxidase by i.v. anaesthetics is in the first instance an immune compromising effect. It would have been very speculative to discuss a possible antioxidant effect of propofol only on the basis of our *in vitro* experiments.

PMA is a well known and accepted stimulus for respiratory burst which acts directly via protein kinase C.[2]

Finally, control experiments (data not shown in article) with the studied anaesthetics and no PMA stimulation excluded preactivation of neutrophils. Thus the hypertonity of the solutions did not affect the results of the particular system of the study.

The effect of three different lipid solutions (concentration 600 $\mu g\ ml^{-1}$) on respiratory burst under different stimuli was investigated in a consecutive study not yet published. We studied long-chain triglycerides (Intralipid 10, Pharmacia), LCT/MCT preparation (Lipofundin MCT 10%, Braun) and omega-3 fatty acid (Omegavenos 10%, Fresenius). Suppression of respiratory burst by all three lipid solutions under PMA stimulation (% mean inhibition: Intralipid, 87.9 (SD 8.5), Lipofundin, 78.8 (17.0), Omegavenos, 84.3 (10.7)) was found to be similar to previously described results.[1] Under stimulation with *E. coli*, respiratory burst was suppressed by Intralipid (8.0 (9.3)) and Omegavenos (9.6 (11.1)) and increased by Lipofundin (−42.7 (21.4)). Therefore, suppression of respiratory burst by lipid solutions seems to depend both on the stimulus and nature of the lipid solution.

## ASA classification and perioperative variables as predictors of postoperative outcome

Sir,—I read with interest the article of Wolters and colleagues[1] and I have a comment on their statistical analysis.

They stated "the Student's *t* test was used to quantify the difference in the means of independent perioperative variables between ASA classifications". This test can be used correctly between no more than two groups and it is not used to quantify the difference but just to verify if a difference between means probably exists.[2]

The authors did not report the SD of values of operation duration (min), intraoperative blood loss, intensive care stay (days) or postoperative stay (days) in relation to ASA, but considering preoperative status in relation to hours of postoperative ventilation they report the following mean (SD) values: arterial hypertension yes 7.3 (37.3), no 6.5 (29.8); previous myocardial infarction yes 13.7 (52.2), no 6.4 (34.3); severe bronchopulmonary disease yes 10.6 (45.5), no 5.7 (32); smoker yes 6.3 (30.8), no 6.9 (37).

Parametric tests such as the Student's *t* test or analysis of variance can be used correctly only if the distribution of the variable is symmetrical; when a variable has only positive values and the SD is greater than the mean, the variable must be considered non-symmetrically distributed,[2] and therefore parametric statistics cannot be used to describe or verify a hypothesis on such data.

If the authors had used logistic regression for specific postoperative complications they would have avoided these problems and they would have obtained more useful results than to define risk factors for indefinite "postoperative complications".

2. Yancey JM. Ten rules for reading clinical research reports. *American Journal of Surgery* 1990; 159: 533-539.

Sir,—We appreciate the comments of Magi on our article. Indeed we used the Student's *t* test to explore observed differences between the means of selected variables for each of two defined subgroups in order to quantify the probability that this differences exists by chance sampling only, as stated in the first sentence on p. 219 "...in relation to ASA (table 6) we found an increase in duration of operation between ASA I and ASA II–IV combined ($P<0.05$) and between ASA II and III ($P<0.05$)...".

In the next step we used explorative *P* values as hints to select some variables as possible predictors for postoperative outcome by modelling the probability of a postoperative complication using a logistic regression model.

We agree with Magi in pointing out some well known general rules of thumb for the correct use of the *t* test, which should be followed, especially when comparing means for small samples.

Additionally, it should be remarked that the methodological properties of the two-sample *t* test may be poor for small samples, even if the data are distributed normally, if sample sizes and variances differ greatly. On the other hand, for sample sizes that are large enough (as for the data in our article) well known implications from central limit theory assure that the *t* test performs well (as for the data in our article) distributions. This "robustness" of the *t* test implies that for "large" samples and without the assumption of normality, the nominal *P* value is approximately the same as the true significance level whenever the null hypothesis holds.

We apologize for giving SD values only for operation duration, postoperative stay and some other variables for the complete sample (c.f. table 2) but not in relation to ASA subgroups. This omission was designed to prevent table 6 from becoming too large.

We again emphasize that the central aim of the study was an attempt to quantify the importance of ASA classification and well known clinical risk factors in the evaluation of complicated surgical outcome by multivariate analysis of clinical data

## ASA classification and perioperative variables: graded anaesthesia score?

Sir,—As Wolters and colleagues[1] pointed out in discussion, a major drawback of the ASA system is assessment of a patient's "correct" ASA classification by different anaesthetists. This has been shown clearly in previous studies[2 3] in which, after consideration of audit, we have concluded that the preoperative status cannot satisfactorily be described by it alone. The situation in obstetric anaesthesia is no better.[4] Wolters and colleagues overcame this problem by using two experienced anaesthetists to classify each case, which is far removed from routine UK practice.

We believe that an improved scoring system needs to incorporate both physical status (chronic health evaluation) and operative risk. It must be both reproducible and simple to use. The present situation could be greatly improved by combining a minimally modified ASA physical status classification with an indication of relative "anaesthesia risk", thereby producing a composite graded anaesthesia score (GAS).

Anaesthesia risk is multifactorial, but attempts to incorporate this into a physical status/chronic health score create difficulties and inconsistencies, particularly in respect of patients suffering

*Table 1* Graded anaesthesia score (GAS). Morbidity/mortality related to anaesthesia provision for patients with chronic stable intercurrent medical conditions is *not* an additional risk. Additional risks include: (a) acute exacerbations/disturbances in chronic disease states; (b) condition for which surgery is required; (c) proposed surgical plan and its urgency; (d) trauma; (e) physiological disturbances; and (f) anaesthesia influencing conditions (for example 2=dental work, pseudocholinesterase abnormalities, URTI etc; 2.5=aspiration risk, normal pregnancy, moderate obesity, chronic airway management problem, age <1 or >80 yr, anaesthesia related allergies etc; 3=malignant hyperthermia susceptibility, moderate physiological disturbances following trauma, sepsis or head injury, pre-eclampsia, etc; 4=acute airway obstruction, eclampsia, severe physiological disturbances following trauma, sepsis or head injury, morbid obesity, etc)

| Chronic health/physical status | Additional anaesthesia risk |
|---|---|
| 1. A normal healthy patient | 1. No additional risk |
| 2. A patient with mild systemic disease | 2. Minor |
| 2.5. A patient with moderate systemic disease | 2.5. Moderate |
| 3. A patient with severe systemic disease that limits activity but is not incapacitating | 3. Major |
| 4. A patient with an incapacitating systemic disease that is a constant threat to life | 4. Life threatening |
| 5. A moribund patient who is not expected to survive for 24 h with or without an operation | |

trauma or severe acute physiological disturbances such as those induced by sepsis.

Remove concern regarding additional anaesthesia risk by grading it separately, concentrate on intercurrent chronic health concerns and the ASA physical status classification system becomes reliable and reproducible requiring but one small modification in respect of a class between II (mild systemic disease) and III (severe systemic disease) to represent the moderate systemic disease which so frequently presents. ASA V is already effectively a composite score.

The GAS is shown in table 1. It can be seen that all but ASA V patients move from a single to a double digit score with significantly improved "risk assessment". This is of value to quality assurance, in assigning the appropriate grade of anaesthetist and to medical audit, producing the consistency which would thereby allow meaningful comparison between units. Thus the normally healthy patient with a dental abscess producing acute airway obstruction is scored GAS 1.4 and the cases listed by Owens, Flets and Spitznagel[2] and Haynes and Lawler[3] can also be easily and conveniently graded.

Having confirmed the simplicity and ease of use of GAS in a pilot evaluation, we believe that the advantages of the score should now be the subject of a large study on a regional or national basis.

4. Plumer MH, Rottman R. How anesthesiologists practice obstetric anesthesia. *Regional Anesthesia* 1996; 21: 49–60.

Sir,—We are well aware of the problem of consistency in the use of the ASA physical status classification by different anaesthetists. Therefore, in this study we attempted to eliminate this inaccuracy. In addition, the ASA system is used by all anaesthetists in our clinic.

In order to mimic a "real-life" scenario, Haynes and Lawler[1] did not provide a definition of the ASA grades to respondents. In this case it would have been interesting to know if the respondents were regular users of the system. However, Haynes and Lawley and also Plumer and Rottman[2] did not provide any information on this point.

In our study, ASA classification was used only in its original meaning to describe physical status, not as an estimation of anaesthetic risk. The perioperative variables representing outcome were mainly surgical or general perioperative complications and were not manifestations of specific anaesthetic risk, for example aspiration, airway obstruction or malignant hyperthermia.

Therefore, the aim of our study was different from the proposed graded anaesthesia score (GAS) which is intended to represent anaesthetic risk.

We would be very interested to see if the prognostic value of GAS can be confirmed statistically in a large study.

## Effect of Sprotte needle orientation on spinal anaesthesia

Sir,—I wish to comment on the study of James and colleagues on the effect of orientation of a Sprotte needle on spinal anaesthesia using 0.5% plain bupivacaine.[1] They demonstrated that when the needle orifice was pointing cephalad, median onset time of sensory block to T4, measured by loss of cold sensation, was significantly faster compared with caudad orientation (5 (interquartile range 3–5) min *vs* 8 (5–9) min, respectively). This is a small but clinically useful difference when rapid onset is required. However, the maximum level of sensory block was similar in all four groups which implies that the distribution of local anaesthetic within the cerebrospinal fluid (CSF) was also similar. This is to be expected as the major determinants affecting distribution of local anaesthetics after subarachnoid administration are the physical characteristics of the local anaesthetic and patient characteristics.[2] The technique of injection is less important although it may play a role

The baricity of 0.5 % plain bupivacaine is slightly hypobaric at body temperature.[3] Plain bupivacaine has been shown to "float" cephalad 80–115 min after injection.[4] If injecting in a cephalad direction delivered a higher dose of local anaesthetic to the trough of the thoracic kyphosis, the drug should then "float" upwards along the cephalad border of the kyphosis to a higher level if the patient is in the supine position. The fact that this did not occur implies that a similar dose of local anaesthetic was distributed towards the trough. Hirabayashi and colleagues have demonstrated that the lowest point of the thoracic hollow is T7–T9, which may account in part for the variable spread seen in clinical practice.[5]

Two reasons may explain the lack of difference in maximum spread of local anaesthetic drug in this study. An injection speed of 5 ml $\text{min}^{-1}$ through a Whitacre needle produced turbulent mixing in an *in vitro* model.[6] Also, changes in body position affect the volume of the extradural venous plexus which can consequently displace CSF.[7] It would be easy to imagine the effect in a confined CSF compartment of these two factors resulting in the drug being thoroughly and similarly mixed whatever the initial direction of the needle orifice.

Other studies investigating the effects of orifice orientation of needles with a lateral eye have produced mixed results regardless of the baricity of the drug used.[8–11] Those studies which demonstrated a higher block with the orifice pointing cephalad did so because patients had no or very little body movement after spinal anaesthesia was performed [8–10] In the study of James and colleagues, patients were placed from the right lateral to the left lateral position, and in another study were changed from the sitting to the lateral position.[1 11]

It is difficult to establish if baricity or bulk displacement of CSF is the major factor responsible for the effects caused by changes in body position. Until a truly "isobaric" local anaesthetic mixture is available (tetracaine crystals which can be dissolved in CSF are not available in the UK) positional effects will always have a prominent role over orifice orientation in determining drug distribution within the CSF. While "non-isobaric" agents are favourable in some circumstances there are arguments against their use.[12]

Finally, the angle of emergence of solutions injected through a modern 25-gauge Whitacre needle into a fluid medium is approximately 35° to the longitudinal axis.[6] The angle is approximately 30° with a 24-gauge Sprotte because of the larger orifice (although the size of orifice has recently been reduced) The clinical consequences of this small difference are unknown but are unlikely to be important as a similar distribution pattern of injectate was produced by both of these needles in an *in vitro* model.

12. O'Callaghan-Enright S, Finucaine BT. Alteration of baricity: is it necessary? *Canadian Journal of Anaesthesia* 1992; **39**: 753–756.

Sir,—We agree that many factors influence the maximum sensory block height achieved after injection of local anaesthetic into the subarachnoid space. Serpell stated that the physical characteristics of the local anaesthetic agent and patient characteristics are more important in determining maximum sensory block than the technique of injection. Our study showed that the technique of injection affected not maximum sensory block but *speed of onset* of block.

The patients we described were pregnant women. The main finding of our study was that the technique of injection for subarachnoid anaesthesia affected the onset time of a sensory block suitable for Caesarean section in women at term. We orientated the side eye of the Sprotte needle cephalad, caudad, right and left lateral, and demonstrated that a cephalad injection produced a significantly faster onset of block. This is a clinically important difference when rapid onset of sensory block is required for Caesarean section.

Maximum block heights achieved were similar regardless of needle orientation so while the speed of onset of block was affected by injection technique, final distribution of local anaesthetic in the CSF is influenced by the many other factors the author mentioned. Posture is particularly important in the pregnant woman at term.[1] We induced subarachnoid anaesthesia in the right lateral position and then turned the women supine with a 20° left lateral tilt and this would enhance the spread of local anaesthetic in the CSF.

## Cardiac arrest after Caesarean section

Sir,—Having read the case report of Scull and Carli,[1] we wish to bring to your readers' attention a similar incident which occurred in our institution recently A 31-yr-old woman was scheduled to undergo an elective lower segment Caesarean section (LSCS) under subarachnoid anaesthesia at 38 weeks' gestation because of a breech presentation. The woman was 163 cm tall and weighed 75 kg.

The patient was premedicated with ranitidine 150 mg and metoclopramide 10 mg, 2 h before operation and 30 ml of sodium citrate 0.3 mol litre$^{-1}$ before induction. After giving 500 ml of colloid i.v., subarachnoid anaesthesia was performed with the patient in the sitting position using 0 5% hyperbaric bupivacaine 2.4 ml injected via a 24-gauge Sprotte needle at L2–3.

The patient lay down on the operating table which was immediately tilted approximately 25° to the left. Arterial pressure before subarachnoid injection was recorded at 129 mm Hg systolic (Dinamap), and after 5 and 10 min was recorded at 114 and 105 mm Hg systolic, respectively. After the second of these readings, ephedrine 6 mg was given i.v. At 10 min block height was T3 bilaterally.

At 15 min as surgery commenced, the patient suddenly complained of severe nausea and became increasingly agitated, talking incoherently and flailing her arms. Arterial pressure had just been recorded at 96 mm Hg systolic, and another dose of ephedrine 6 mg was given i.v. After this the patient continued to flail her arms about, but had stopped talking.

After a few seconds of arm-waving, she collapsed and very rapidly became cyanosed. Her pupils were not dilated at this or at any later time. The ECG monitor showed a bradycardia of 15–20 beat min$^{-1}$, but arterial pressure was not measured at this time. Oxygen saturation was noted to be 70%.

Cricoid pressure was applied and manual ventilation with 100% oxygen started via a face mask. The following drugs were given in rapid sequence: atropine 0.6 mg, ephedrine 18 mg, thiopentone 100 mg and suxamethonium 100 mg, and the patient's trachea was intubated with a 8.0-cuffed oral tracheal tube The pulse oximeter showed a rapid increase in saturation from 70% to 100% before intubation, and this was maintained above 97% after intubation. Anaesthesia was maintained with 1% isoflurane and 50% nitrous oxide in oxygen. Arterial pressure was recorded at 170 mm Hg systolic just after intubation, with a heart rate of 110 beat min$^{-1}$.

The operation continued uneventfully and 1 h 15 min after the subarachnoid injection the patient's trachea was safely and uneventfully extubated. The patient could feel a dull ache in the area of the incision, although the block was not formally tested.

The patient was subsequently interviewed at length. She remembers being unable to breathe or communicate this problem but being still able to move her arms, which she did in order to attract attention. She remembers the mask being applied to her face and air being blown through her nose.

While these are unusual features, this case probably also represents a reduction in venous return (because of aorto-caval compression) leading to bradycardia, hypotension and loss of consciousness. Subarachnoid block has increasingly become the anaesthetic of choice for Caesarean section, particularly in those patients in whom intubation is predicted to be difficult. What this and other cases of respiratory difficulty after subarachnoid anaesthesia[2–6] should remind us is that there is occasionally a requirement for tracheal intubation and any anaesthetic plan should take this into account. Care should also be taken to avoid all causes of a reduced venous return.

## Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model

Sir,—Iwai and his colleagues[1] have matched the Monod–Wyman–Changeux (MWC) ligand-receptor model to sigmoid dose–response curves for anaesthetics. The model represents the way in which the proportion of receptor sites occupied increases with increasing concentration of ligand (anaesthetic) Therefore, it seems logical to match the model to the response of a single cell to an anaesthetic when that response can be measured, as in the case of a $Cl^-$ current. Indeed, it is fascinating to see that, when the authors matched the model to the response of induced $Cl^-$ currents in single cells to halothane, they obtained plausible values for the variables of the MWC model.

If depth of anaesthesia can be measured in a single, whole organism, it would also be reasonable to extend the approach to matching the response of that organism to an anaesthetic. Indeed, mathematically, the model can be matched to any sigmoid curve, so it is not surprising that when the authors matched a dose–response curve for isoflurane in humans,[2] they obtained a close match to the reported $EC_{50}$ (MAC) and $EC_{95}$ values.

However, I question the logic of this extension from the response of a single cell or a single organism to the response of a population. The doses are of a comparable nature; the responses are different: in individuals, percentage of maximum response; in a population, percentage of individuals in whom a particular response is present. For example, MAC is the concentration at which 50% of patients fail to respond to a noxious stimulus, classically surgical incision.

The relevant distinction between single organisms and populations is as follows. The variation in the concentration required to produce different $Cl^-$ currents in a single cell, or different depths of anaesthesia in a single patient, arise from the need for different degrees of occupancy of some receptor (or possibly combination of receptors).[3] On the other hand, the variation in concentration required to anaesthetize different patients is presumably as a result of variation in genetic and, perhaps, nutritional and environmental factors.

To take an extreme case, suppose that the dose–response curve for depth of anaesthesia in a single organism has a slope which can be matched with an MWC curve with plausible values for its variables. Suppose then, that 1000 clones of that organism were produced and reared under identical conditions. Those clones would all reach any given depth of anaesthesia (such as lack of response to a noxious stimulus) at the same concentration. Thus at just less than the critical concentration, none of the organisms would respond; at just greater, all would respond. Therefore, the population dose–response curve (for the proportion of organisms responding) would have infinite slope, and yet the dose–response curve (for depth of anaesthesia) for each individual would still have the original slope.

The results of this study are very interesting and will, I hope, stimulate further work in this area. However, I think that the authors are a long way from demonstrating that the variables of reaction kinetics related to depth of anaesthesia can be deduced from population dose–response curves.

Sir,—Dr Mapleson questioned the logic of our extension of the treatment based on the Monod–Wyman–Changeux (MWC) model from *in vitro* cases to *in vivo* cases in our article.[1] He mentioned that the dose–response of a population is different from that of a cell: if clones were reared under the same conditions, the population dose–response curve would have infinite slope, and yet the dose–response curve for each individual would still have the original slope. Dr Mapleson's argument is correct, provided that some additional integrated effects do not take place in an organism. He also suggested that the variation in the concentration required to anaesthetize different patients is caused by genetic and, perhaps, nutritional and environmental factors. It is plausible. However, we are aiming to understand the mechanism of anaesthesia on the basis of molecular scheme and our article is one of such studies. As mentioned in our article, we assumed that the variation in concentration came from the variation in fractions of active receptor molecules occupied by anaesthetics between individual patients from a molecular viewpoint.

## Failed intubation drill

Sir,—We read the article by Hawthorne and colleagues[1] with interest.

We agree that there may be a cultural explanation for the disproportionate representation of Afro/Caribbean women presenting for Caesarean section under general anaesthesia. It is well known in the West Indies that West Indian women are reluctant to accept extradural analgesia; indeed, there is no extradural service in our hospital. Further, there may be a higher Caesarean section rate among Afro/Caribbean women because of the increased angle of inclination which predisposes to malposition.[2] On the basis of the above, one may expect to find a higher rate of Caesarean sections under general anaesthesia and by inference more frequent failed intubations.

In the St James' Hospital failed intubation drill it is stated that on deciding that intubation has failed, the patient is turned on her side and placed head down. We disagree with turning the patient on her side and with placing her head down before the return of spontaneous respiration for the following reasons: (a) the key principle in the management of a failed intubation is oxygenation without aspiration.[3] In order to achieve oxygenation, it may be necessary to ventilate the patient's lungs with a bag and mask until the action of suxamethonium terminates; (b) ventilation would be easier if the patient were kept in the supine position with the wedge in place In the head down position, splinting of the diaphragm is aggravated with concomitant reduction of lung compliance thus making lung inflation more difficult; (c) junior anaesthetists are far more experienced at holding a mask and ventilating patients' lungs in the supine than in the left lateral position; and (d) Rosen cautions against turning the patient on her side before the return of spontaneous respiration because this is often impractical and it may be difficult to ventilate the lungs in the lateral position.[4] Afro/Caribbean women at term are quite heavy (average weight in our hospital is 85 kg). It may be difficult to turn her on her side and manage the airway at the same time, and it is quite possible that in the turning process the patient may fall off the table.

# BOOK REVIEWS

*Pharmacology in the Practice of Anaesthesia.* L. KAUFMAN AND P. V. TABERNER (editors) Published by Arnold, London. Pp. 689; indexed; illustrated. Price £75.00.

This textbook is the latest entry in a very competitive area of pharmacology textbooks relating to anaesthesia and is edited by an anaesthetist and a pharmacologist The 675 pages of text are divided into 12 sections, containing a total of 39 chapters to which 52 authors have contributed. The authors are principally British; there is one contribution from each of the USA, Canada and Australia.

The 12 sections of the book are divided into general pharmacology, anaesthetic agents, drugs acting on synapses and neuroeffectors, cardiovascular system, respiratory system, central nervous system, management of pain and inflammation, peripheral organ systems (blood, kidneys and GI tract), endocrine system, chemotherapy, sterilization and finally, adverse effects of drugs. Each of these sections consists of usually three or four chapters. Within each chapter there are a reasonable number of figures and tables and each section concludes with, in the majority of cases, a list of five or six texts (often other textbooks) under the heading, recommended reading, although in a few chapters there is an extensive reference list.

I am afraid I found this textbook rather disappointing I had high expectations of it given its editorship but I found it both difficult to read and lacking in information in some areas. One of the approaches to reviewing a textbook is to use it as a reference manual over a period of time. In doing this, I found that while in general the anaesthetic drugs are dealt with reasonably well (although often in short note form) there are other areas where the information is rather diffuse and there are confusing cross-references in the text. Examples of these are: in the i.v. anaesthetic agents, each agent is dealt with in less than one page and the pharmacological information is comprehensive but not exhaustive. Examples of the gaps that I encountered were in the relationship to adrenoreceptors where after a virtually unlabelled diagram in the first chapter, the text said it would be explained in further chapters. Despite searching I could not find a comprehensive description of G-protein involvement and the method of transmission across the cell membrane. In the chapters on opioids, there is confusion between the authors of two consecutive chapters as to whether sigma receptors should be included, with the first stating they are not opioid receptors as they are insensitive to naloxone and some 12 pages later the second author notes that they are opioid receptors which are similar to kappa in being weakly sensitive to naloxone. There are some good sections within this book and indeed overall this reflects the difficulty of multi-authorship textbooks.

There are now seven or eight textbooks dealing with anaesthetic pharmacology and I am not sure how this textbook will fare in this very competitive market.

*C. S. Reilly*

*Reflex Sympathetic Dystrophy: A Re-appraisal.* W. JANG AND M. STANTON-HICKS (editors). Published by IASP, Seattle. Pp. 249; indexed; illustrated. Price $55.00.

In 1993, a conference in Florida, USA, addressed the controversy surrounding reflex sympathetic dystrophy (RSD) and a consensus was reached concerning a re-definition of this complex syndrome. The topics included in *Reflex Sympathetic Dystrophy: a Re-appraisal* were chosen during discussion after this conference but the editors are keen to emphasize that the book is not simply a description of the proceedings of that conference. They are to be congratulated in persuading such an eminent and international panel of authors to contribute to the volume.

The first chapter describes very clearly and comprehensively the mechanisms and hypotheses surrounding RSD. It is an excellent opening chapter and provides the background for the rest of the book. Despite the consensus to adopt the term complex regional pain syndrome (CRPS), both terms are used throughout the book. For simplicity, the reviewer will use CRPS only.

The second chapter describes the clinical characteristics of CRPS (both I and II) based on data collected from two clinics in Germany. A comprehensive analysis includes factors such as changes in skin temperature under various conditions and results of diagnostic tests. Although this is a very localized audit, it is likely that the results and conclusions will be of great interest to all practitioners worldwide. Similar data from a USA clinic follow and the authors have arrived at a recommendation on the diagnosis of CRPS based on a clinical and laboratory approach.

The final chapter in this section deals with CRPS in children, the differential diagnosis of the syndrome and the development of a diagnostic algorithm. These early chapters give the reader a very wide appreciation of the syndrome of CRPS and the controversies surrounding its aetiology and diagnosis.

The book now considers the influence of animal models on our understanding of CRPS. Three animal models of neuropathic pain (chronic constriction injury, partial nerve transection and spinal nerve transection) are reviewed. The authors have selected data relevant to CRPS and have not reviewed extensively other less relevant data. I thought this chapter was particularly good; the literature was reviewed critically and important conclusions emerged.

The various mechanisms mediating pain in neuralgia are considered next. This difficult area is discussed well, aided by many very helpful figures and diagrams. A logical next step is to consider sensory testing in patients with CRPS; many methods of testing are considered and all are possible at the bedside or in the clinic.

Chapters on the use of placebo and psychological issues in CRPS follow. Again, these are excellent contributions and it is concluded that the "RSD personality" is not substantiated. Finally, there is a small and precise review on the use of regional anaesthesia for diagnosis of CRPS.

I found this book a delight to read; there cannot be a better treatment in a relatively small publication of this complex area. I am sure it is essential reading, not only for those who are training in pain management, but for those who are already established. It certainly represents very good value for money.

## EDITORIAL I

### Extracorporeal membrane oxygenation, a favourable outcome?

Extracorporeal membrane oxygenation (ECMO) uses a pump oxygenator to provide prolonged respiratory or cardiac support in the intensive care unit. Since the first successful use of ECMO was reported in 1972[1] there have been conflicting opinions on the use of ECMO to salvage moribund patients. The American National Institute of Health (NIH) study showed no survival advantage compared with conventional treatment[2] and a virtual cessation of ECMO in adults followed the publication of this study. However, a mortality rate of more than 60% for ARDS patients[3] forced intensivists to continue to search for successful therapies; partial liquid ventilation,[4] inhaled nitric oxide,[5] prone ventilation[6] and pressure control inverse ratio ventilation (PCIRV)[7] have all been advocated. All of these modalities may result in improved blood-gas tensions, and some in improved survival.[7] Unfortunately, while such improvements may be statistically significant we are still faced with the clinical problem of a mortality rate of 82%[8] to 55%[7] from severe ARDS. It is likely that the small response in terms of survival lies in the fundamental problem that any treatment which relies on the injured lung to maintain gas exchange will become increasingly ineffective as lung disease becomes more severe, mortality increasing from 33% with moderate lung injury to more than 82% with severe injury,[8] because of continued barotrauma,[9] volutrauma[10] and oxygen toxicity,[11] all combining to produce ventilator lung injury.[12] Eventually a point is reached when the airway pressure, minute volume and $F_{I_{O_2}}$ necessary to maintain life exceed the lungs capacity to resist the continual and repeated insults of ventilation, and thus the patient perishes. We return therefore inexorably to the concept that some form of extrapulmonary gas exchange coupled with gentle ventilation, "lung rest", which causes no further damage to the "baby lung"[13] is the most rational treatment for refractory severe respiratory failure, provided any significant morbidity associated with the treatment itself can be minimized or eliminated. The intra-vena caval oxygenator (IVOX)[14] needs further development in terms of gas transfer capability and clinical ease of operation before it becomes a viable option, as in its current form only modest reductions in ventilator settings, which is the goal of extrapulmonary gas exchange, are possible. Thus ECMO remains the only current technique which can support gas exchange outside the lung, and allow the lung to be rested and recover. Numerous case series, summarized by Lewandowski and colleagues,[15] have shown that ECMO, including extracorporeal carbon dioxide removal (ECCO2R) can result in similar or reduced mortality (51%) compared with conventional treatment (56%)[15] but is usually applied only to patients with more severe disease. Unfortunately the intensive care community in general remains unconvinced as to the purported benefits of ECMO, as there are difficulties in comparing different historical series of patients treated in different hospitals, at different times, with different severities of illness and different treatment techniques. A recent attempt to solve this conundrum was the randomized study of ECCO2R *vs* PCIRV[16] conducted by Morris and colleagues. No significant difference was apparent between the 58% mortality in the PCIRV group and the 69% mortality in the ECCO2R group. This study was interpreted by the authors and the sceptics to confirm the findings of the earlier NIH study, that ECMO is ineffective, but the methodological and technical considerations discussed by Rossaint and colleagues in this issue of *British Journal of Anaesthesia*[17] make this conclusion unguarded. However, it is safe to conclude from the data of Morris and colleagues that low-flow ECCO2R, even when provided by an inexperienced team, and when complicated by haemorrhage and technical problems, is as good as the very best PCIRV.

Full flow (i.e. enough to provide oxygenation and carbon dioxide removal) veno-venous ECMO has been shown to be effective in supporting gas exchange, allowing a reduction in ventilation and $F_{I_{O_2}}$.[15 17–19] While there are reasonable concerns on the use of historical controls when comparing different treatments, common sense indicates that if these results have been duplicated by numerous different ECMO providers around the world, and if consultants continue to refer their moribund patients for ECMO, the most likely explanation is that ECMO is effective.

This conclusion is supported by comparing our own series of adult respiratory patients with the patients described by Morris and colleagues.[16] For the first 50 patients referred to us for treatment, mean $P_{a_{O_2}}/F_{I_{O_2}}$ ratio was 8.7 (SD 4.9) kPa, not significantly different from the control group of Morris and colleagues (*t* test, $P=0.741$), the Murray score[20] was 3.4 (0.5) and hospital mortality 34%, a significant improvement over the best published series of patients undergoing conventional ventilation (58% mortality)[16] (chi-square 11.71, $P=0.0006$).

Assuming that one accepts the benefits of ECMO with lung rest, the problem of transporting the critically ill, hypoxic patient to a hospital providing ECMO still remains. Our own experience is that while this may often be possible, patients who are extremely hypoxic, especially those who are dependent on inhaled nitric oxide, can be very unstable during transfer, and usually need to be "crashed on" to ECMO on arrival at our hospital. The answer to this problem is initiation of extracorporeal support at the referring hospital and transfer of the patient back to the ECMO centre on ECMO in a calm, unhurried manner. Rossaint and colleagues[16] have reported their experience with eight extremely hypoxic patients transported on veno-venous ECMO; there were six long-term survivors. A 25% mortality for patients with an $Pa_{\mathrm{O}_2}/FI_{\mathrm{O}_2}$ <6.7 kPa and a mean Murray score of 3.59 is impressive even if transport were not involved.

This experience confirms the observation of other ECMO transport teams, that if the patient's gas exchange can be supported extracorporeally, patients can be stabilized and transported many thousands of miles in safety.[21,22] Other authors have elected to use mainly veno–arterial perfusion during transport to provide more haemodynamic control, and then convert to veno-venous support when the patient has been stabilized back at the ECMO centre. Another curious fact to emerge from series of patients transported on ECMO is that the outcome in this group of patients too ill to be moved by conventional means is often better than patients transported to the ECMO centre using positive pressure ventilation. The University of Michigan group reported a mortality rate of 14% for adult ECMO transport patients[21] compared with 43% for other adult ECMO patients.[23] This may indicate that patients should be referred for ECMO earlier, before severe hypoxia is established, or alternatively that mobile ECMO should be used more widely.

Mobile ECMO is now available in the UK, as the Heartlink ECMO centre at Glenfield Hospital, Leicester, now has transport facilities. The mobile ECMO system has been used once thus far to transport a 2-yr-old boy with Kawasaki syndrome to a transplant centre; the patient remained stable during transport despite absent underlying myocardial function but, unfortunately, heart transplantation 1 week later was not successful.

Intensivists who are sceptical about the potential benefits of ECMO should audit (and publish) the mortality of their patients with hypoxic acute respiratory failure. If they can show consistently better mortality than 34% for a mean $Pa_{\mathrm{O}_2}/FI_{\mathrm{O}_2}$ of 8.7 kPa and Murray score of 3.4 then they are justified in continuing to treat their patients conventionally; if however they cannot, it is in their patients' best interests to consider the benefits of ECMO when conventional treatment is failing, and before terminal ventilator lung injury has occurred (7 days).

Unfortunately, many intensivists remain sceptical. Indeed the editorial accompanying the publication of the UK Collaborative Neonatal ECMO study,[24] stated that ECMO was an "unfavourable outcome".[25] If one believes this then considering the evidence one must therefore consider death and disability to be preferable to ECMO. We do not believe this to be the case.

## EDITORIAL II

# Are there new solutions to old problems with weaning?

Delayed weaning from mechanical ventilation is a problem in every intensive care unit. Not only is this associated with an increased mortality and risk of pneumonia,[1] pulmonary emboli and psychological disturbances,[2 3] but it also has implications for the cost of care and the use of scarce resources.

The question of how to hasten weaning raises several inter-related issues that have a major bearing on our approach to the patient undergoing ventilation. The first is the question of what is meant by the term "weaning". It usually implies two separate but closely related aspects of care, termination of mechanical ventilation and removal of any artificial airway. This may lead to confusion because the definition of mechanical ventilation is becoming more blurred with the increasing variety of modern techniques of support. Continuous positive airway pressure (CPAP), for example, is not strictly a form of ventilation but should a patient with CPAP and an orotracheal tube be considered to be weaned? If the tube is removed and CPAP is provided via a face mask, should the patient now be considered to be weaned although he or she is receiving the same support physiologically? Similarly, is the patient who uses a nasal positive pressure ventilator each night in the home after discharge from an ICU weaned or not? A more satisfactory approach would be to discontinue the term "weaning" and address its two components separately—can independent ventilation and tracheal extubation be achieved?

Mechanical ventilation is required for as long as the load on the respiratory pump exceeds its capacity. The load can be reduced by lowering metabolic rate by treating any infection, and relieving the patient's fear and anxiety. The resistive work of breathing can be reduced by treating reversible airflow obstruction and aspirating secretions in the tracheobronchial tree, and the elastic work can be minimized by treating pulmonary oedema or pneumonia, and avoiding hyper-inflation. Conversely, respiratory drive may be improved by reducing sedation, avoiding sleep deprivation or metabolic alkalosis, and by normalizing arterial $P\text{CO}_2$. Respiratory muscle function can be optimized by attention to the position of the patient, especially if the diaphragm is weak, relieving malnutrition, and correcting hypoxaemia, hypercapnia, acidosis, hypercalcaemia, hypophosphataemia and hypomagnesaemia.

But is this load:capacity concept useful in practice? It has led to the use of several predictors for successful "weaning" such as tidal volume $>5$ ml kg$^{-1}$, FEV$_1$ $>10$ ml kg$^{-1}$, vital capacity $>10$–15 ml kg$^{-1}$, maximum inspiratory pressure $>20$–30 cm $H_2O$, minute ventilation $<10$ litre min$^{-1}$ and a maximum voluntary ventilation of twice the resting minute ventilation.[4 5] Recently more complex measures, including ventilatory frequency to tidal volume ratio and an index combining thoracic compliance, respiratory frequency, $Pa_{O_2}$ to $PA_{O_2}$ ratio and maximal inspiratory pressures have been developed[6] but they, in common with simpler indices, have been found to be of limited value in predicting the success of weaning.[7–9]

There are several reasons why these predictors fail. First, most of the measurements require a maximal effort which is hard to ensure in ill patients in an ICU. Second, there are technical difficulties which have led to poor repeatability of measurements[10] and even if the values are accurate the question remains as to whether or not all important factors relevant to weaning are being measured. None of the methods takes into account the psychological state of the patient or the far reaching autonomic and humoral responses which occur particularly during the first 24 h after tracheal extubation and which alter, for instance, fluid and electrolyte balance, deadspace: tidal volume ratio, cardiac output and regional lung perfusion.[11]

The airway may need to be retained, irrespective of whether or not ventilatory support can be discontinued in order to bypass upper airway obstruction or, more commonly, because of doubt about the patient's ability to cough and swallow. This is a problem, particularly in chronic neuromuscular disorders but also results from both translaryngeal intubation, which may cause vocal cord oedema and ulcers,[12] and tracheostomy. A tracheostomy impairs the elevation of the larynx with its associated opening of the crico-pharyngeal sphincter[13] and also increases the threshold for the reflex for laryngeal closure in response to supraglottic stimulation.[14 15] Co-ordination between the respiratory and swallowing related functions of the larynx is impaired and the risk of aspiration increases.

The immediately apparent problem is how to assess the safety of tracheal extubation while the airway remains in place. The gag reflex, swallowing ability and strength of "coughing" give some information. If there is no preceding upper airway obstruction or known difficulty in swallowing or coughing, and particularly if the period of intubation is short, it is reasonable to extubate the trachea when mechanical ventilation is no longer needed and to observe the patient's upper airway function. The risks are, however, greater if intubation has been prolonged and failure to recognize bulbar problems is a frequent cause of re-intubation.

In the presence of bulbar dysfunction the conventional approach is to maintain the tracheal or tracheostomy tube cuff inflated in order to protect the airway. It is, however, only partially effective in achieving this[16] and tends to perpetuate laryngeal and pharyngeal dysfunction. The opposite strategy of cuff deflation should be considered. Although there is little direct evidence, this probably improves the co-ordination of the laryngeal and pharyngeal muscles through reinstating the respiratory function of the larynx and enabling speech to occur. The air passing through the upper airway probably initiates other currently ill defined reflex actions which improve upper airway co-ordination. The risk of aspiration can be minimized in the early stages by only partially and intermittently deflating the cuff. However, cuff deflation is probably the single most underrated and important step in improving upper airway function in the patient whose lungs are ventilated and it should have a central place in the preparatory phase of weaning.

What can be done to swing the balance between the load and capacity of the respiratory pump in favour of the latter? Does the method of ventilation affect the patient's progress or does it have a purely supportive rather than a therapeutic role? Mechanical ventilation certainly does have a variety of cardiorespiratory effects on, for instance, ventilation:perfusion matching, lung volumes and the work of breathing, but these are largely transitory. They may keep or put the patient in a position from which weaning may take place but they do not alter the balance between the load and capacity of the respiratory pump after tracheal extubation or cessation of ventilatory support. It does have two effects which may, however, hasten the moment of weaning. The ventilatory response to hypercapnia increases if arterial $P\text{CO}_2$ is normalized, and respiratory muscle function can also be modified. Respiratory muscle fatigue is avoided normally by adaptation of the central respiratory controlling mechanisms but it is probably wise to try to avoid the respiratory muscles performing near-fatiguing work during mechanical ventilation. Minimizing respiratory muscle work is thought to be helpful in the early stages of an acute illness and when the patient is systemically unwell but after this the strategy should be changed to progressively increase the work of breathing according to the patient's capacity. The aim is to increase respiratory muscle strength and endurance, reverse any disuse atrophy and improve the co-ordination of the different muscle groups in order to aid the weaning process.

It is, therefore, important to select a method of ventilation that both effectively normalizes blood-gas tensions and enables the respiratory muscles to be rested or conditioned as appropriate. A range of partial support techniques such as assist control, SIMV, with or without pressure support, and pressure support ventilation are in widespread use.[17] The work of breathing can be graduated with each of these techniques but the type of work carried out by the patient is different in each case. There are remarkably little data comparing these methods but pressure support ventilation appears to be associated with a shorter period of intubation[18] and minimizes the risks of diaphragmatic fatigue.[19] Addition of pressure support to SIMV has little influence on weaning.[20] T-piece weaning is also used widely, although there are conflicting data as to whether or not this is more effective than pressure support ventilation or CPAP.[21–23]

There are now a wide variety of positive pressure face and nasal masks and mouth pieces[24] and negative pressure techniques using a tank, jacket or cuirass ventilator which are well established.[25] These non-invasive interfaces are being used increasingly to assist weaning but what do they add to conventional tracheal and tracheostomy tubes? A tracheostomy reduces the deadspace and, in common with non-invasive techniques, enables sedation to be withdrawn; if the cuff can be deflated, speech, swallowing and laryngeal co-ordination improve to a variable degree. The non-invasive methods, nevertheless, have two important advantages: they do not require an artificial airway, which impairs coughing, swallowing and speech, and they can also be used intermittently which makes them suitable for patients who benefit from gradually increasing periods of independent ventilation.

Non-invasive techniques should be considered if progress with the conventional interfaces slows or stops.[26 27] They can be introduced gradually while the tracheostomy is in place, although the positive pressure methods require the cuff to be deflated. They are, however, usually unsuitable if the patient is unconscious, unco-operative, requires continuous ventilation for more than 2 or 3 days, or has a poor cough with profuse secretions. They do not protect the airway and a risk of aspiration is generally considered to be a contraindication to their use. This potential difficulty can, nevertheless, be overcome. The first step is to reduce the risk of aspiration by giving the patient nothing by mouth, reducing the volume of saliva (by administration of propantheline or a tricyclic antidepressant, for example) and by feeding through a gastrostomy. The cuff on the artificial airway can then be deflated, often only partially or intermittently at first, and if aspiration does not occur ventilation using a nasal or face mask can be initiated. When this is established the tracheal or tracheostomy tube can be removed and ventilation continued non-invasively. This may be required for a few days or, particularly in chronic neuromuscular disorders, it may be needed in the long term, but usually only at night.

This approach brings together the parallel tracks of ventilatory support and upper airway management. Their integration is often the key to delayed weaning but this may still be impossible unless a broad approach to rehabilitation is applied.[28] Attention should be paid to nutritional support and mobilization, but especially to the patient's psychological needs. The ability to speak when the cuff is deflated and encouragement that an independent life outside hospital is possible are important factors in improving the patient's morale. A normal sleep–wake cycle should be established and sleep deprivation, which is unavoidable in intensive care units because of the almost continuous sensory stimulation,[29] relieved.

Where does this leave the traditional concept of weaning as cessation of respiratory support or extubation. It is clear that these two events are only points in the continuum of care. They are preceded by the preparation phase in which both the physical and psychological aspects of care are attended to and are followed by the rehabilitation phase and in some patients long term, usually nocturnal, non-invasive ventilatory support at home. It is important to distinguish in the preparation stage between purely supportive care and treatments which hasten the time of weaning. Ventilatory support and tracheal extubation, the two separate aspects of weaning, should be assessed separately but their treatments should not simply be provided in parallel but should be closely integrated. A central aspect of integrative weaning is deflation of the cuff of the artificial airway. This not only improves upper airway function but makes positive pressure non-invasive ventilation feasible. Progress through these stages requires complex psychological adjustments which can be particularly difficult if the patient is sleep deprived as a result of the general level of activity on the intensive care unit.

This broad view of the problems of delayed weaning can produce results which are superior to conventional methods.[30] Much work remains to be done to assess the relative importance, precise indications for and mechanisms of action of each of the components of these new approaches. The expertise and facilities that are needed range from those of an intensive care unit to those of both a home ventilation and a rehabilitation unit. The full range of resources are therefore currently concentrated in only a few specialist centres, but may prove to be required more widely in the future.

CLINICAL INVESTIGATIONS

# Extracorporeal membrane oxygenation for transport of hypoxaemic patients with severe ARDS

R. ROSSAINT, D. PAPPERT, H. GERLACH, K. LEWANDOWSKI, D. KEH AND K. FALKE

**Summary**

Conventional inter-hospital transfer of patients with severe acute respiratory distress syndrome (ARDS) in need of extracorporeal membrane oxygenation (ECMO) may be risky and in severe hypoxaemic patients may be associated with cerebral hypoxia and death. Therefore, we began a phase 1 study to evaluate the feasibility, complications and outcome of inter-hospital transport of these patients using veno-venous ECMO. Eight patients with severe ARDS and a $Pa_{O_2}/FI_{O_2}$ <6.7 kPa at a PEEP ⩾10 cm $H_2O$ were placed on a mobile ECMO at the referring hospital. The 495 (SD 123) km inter-hospital transport via a special ground ambulance took 341 (151) min. After transfer, blood-gas tensions were improved in spite of less optimal ventilator settings, compared with data before the start of ECMO. No significant complications occurred. Six patients survived and were discharged from hospital; two patients died because of multiple organ failure. We conclude that initiation of ECMO in hypoxaemic patients before inter-hospital transfer is feasible and enables safe transport to an ECMO centre. (*Br. J. Anaesth.* 1997; **78**: 241–246).

**Key words**

Lung, acute respiratory distress syndrome. Ventilation, mechanical. Hypoxaemia. Monitoring, extracorporeal circulation. Complications, mortality. Intensive care.

The acute respiratory distress syndrome (ARDS) is a rapid and severe alteration in lung structure and function characterized by hypoxaemia, reduced respiratory compliance, pulmonary hypertension and diffuse interstitial infiltrates.[1 2] Since its first description by Ashbaugh and colleagues in 1967, the mortality rate of this syndrome remains greater than 50%, despite extensive clinical and laboratory research efforts.[3–5] Among other unknown factors, this high mortality may be influenced by the disease itself, in addition to iatrogenic factors such as ventilator settings with high airway pressures, large tidal volume and high inspiratory oxygen concentrations ($FI_{O_2}$).[6 7] Therefore, today we aim to reduce peak airway pressure, tidal volume and use lower inspired oxygen concentrations. Conventionally, it is now customary to use pressure- or volume-limited ventilation, or both, with positive end-expiratory pressure (PEEP), body positioning, including prone position, differential lung ventilation, avoidance of fluid overload and acceptance of increased partial pressure of carbon dioxide.

Should these therapeutic measures fail to improve pulmonary gas exchange, extracorporeal lung support has been advocated in the treatment in patients with severe, but potentially reversible, acute respiratory failure.[8 9] As this technique requires special equipment and knowledge, centres for advanced treatment of ARDS have arisen. However, conventional inter-hospital transfer of patients in need of extracorporeal membrane oxygenation (ECMO) can be risky and in severely hypoxaemic patients ($Pa_{O_2}/FI_{O_2}$ <6.7 kPa) may be associated with cerebral hypoxia and death. Therefore, we began a phase 1 study to evaluate the feasibility, complications and outcome of inter-hospital transport using ECMO in this group of patients.

## Patients and methods

This investigation was performed at the Virchow-Klinikum of the Humboldt-Universität with the approval of the institutional Ethics Committee. Informed consent was obtained from each patient's family.

Patients were included in the study if they suffered from severe ARDS, that is a Murray score ⩾2.5[10] and fulfilled the modified fast entry criteria of the US National ECMO study[11] ($Pa_{O_2}/FI_{O_2}$ <6.67 kPa at a PEEP ⩾10 cm $H_2O$ for >2 h) despite various trials to optimize pulmonary gas exchange. Patients were excluded from the study if they had contraindications to ECMO which include extremely poor prognosis because of the underlying disease (malignancy, unresolvable surgical problems), immunosuppression, assured irreversible damage of the central nervous system, severe chronic pulmonary disease,

*This article is accompanied by Editorial I* primary cardiogenic pulmonary oedema and advanced age (>60 yr). Additional organ failures, such as cardiac, hepatic, renal, CNS, gastrointestinal and haematological failure were assessed using grade II definitions of the score of Goris and colleagues.[12]

From June 1993 to October 1995, nine patients fulfilling the above criteria were referred to our hospital for extreme respiratory failure unresponsive to conventional treatment. The severity, duration and assumed consequences of hypoxia, and other organ failures were assessed by telephone. As one of the nine patients died within 2 h after the first phone call, there were eight patients (table 1) to be transferred to our intensive care unit (ICU).

### TRANSPORT FACILITIES

The ECMO team went to the referring hospital by ground ($n=2$) or air ($n=6$) transit depending on the distance to the referring hospital. The ECMO team comprised two anaesthetists and one nurse who were experienced with ECMO techniques. A large bus equipped as a mobile ICU was used for inter-hospital transfer of patients from the referring hospital to our hospital. This bus contained a blood-gas, haemoglobin and electrolyte analyser (ABL 505, Radiometer, Copenhagen, Denmark), a monitor system (Siemens Elema, Lund, Sweden), infusion pumps and a bed fitted with a Siemens 300 ventilator (Siemens Elema, Lund, Sweden), an independent power and gas supply, and a portable monitor system (Siemens) with ECG, arterial and pulmonary artery pressures and pulse oximetry (fig. 1).

### EXTRACORPOREAL BYPASS AND CANNULATION TECHNIQUE

After arrival at the referring hospital, the patient's condition was assessed by the physician, whereas the nurse started immediately to prepare the extracorporeal bypass system. In three patients, a pulmonary artery catheter was introduced and central venous and arterial catheters were changed; in all patients, a short trial was undertaken to improve ventilator settings, which included a test with different PEEP levels and I:E ratios. If $Pa_{O_2}/FI_{O_2}$ remained less than 6.7 kPa at a PEEP $\geq 10$ cm $H_2O$, veno-venous ECMO was initiated. Cannulation was not performed in the operating theatre but in the ICU with the patient in bed. For venous access, 21F cannulae (Biomedicus) were used for adults and 17F cannulae (Biomedicus) for children. Blood was drained via one or—in order to achieve higher extracorporeal blood flows—two spring wire reinforced cannulae introduced percutaneously via the femoral vein, with one cannula placed in the inferior cava and, if possible, a second cannula advanced to the iliac bifurcation. Blood was drained passively into a collapsible reservoir. This reservoir was equipped with a Servo switch to stop the pump if the reservoir collapsed. From here, blood was pumped actively by an almost occlusive roller pump (Stöckert, Germany) through a microporous membrane lung (Medronic Maxima, Anaheim, CA, USA) which was ventilated with oxygen 3–6 litre $min^{-1}$. Oxygenated blood was then returned to a cannula, also introduced percutaneously from the right jugular vein (seven patients) or from the right subclavian vein (one patient) and advanced to the superior cava. All parts of the extracorporeal system were coated with heparin. The extracorporeal flow rate was adjusted to 1.8 litre $min^{-1}$ in children and to 3 litre $min^{-1}$ in adults. Blood temperature was regulated extracorporeally by a heat exchanger and maintained at 36 °C. Continuous monitoring of pressure before and after the membrane lung allowed detection of a kink in the tubing, unintended reduced extracorporeal blood flow or disconnection within the extracorporeal bypass circuit. All electrical parts of

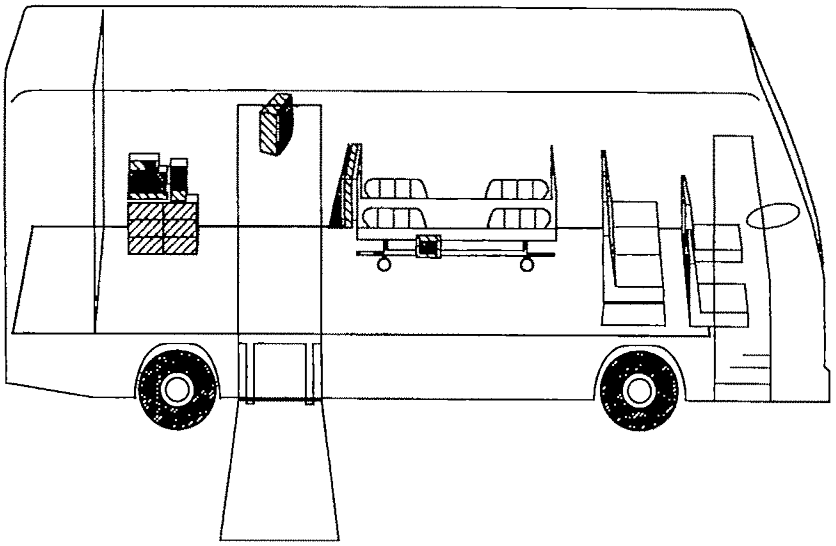

*Figure 1* Intensive care ground ambulance. The bus is equipped with a blood-gas, haemoglobin and electrolyte analyser (in the back of the bus), monitor system, infusion pumps and a bed fitted with a Siemens 300 ventilator, power pack and gas supply, and a portable monitor system with ECG, arterial and pulmonary artery pressure facilities in addition to pulse oximetry. The patient and mobile ECMO are moved into the bus at the same time via a loading ramp.

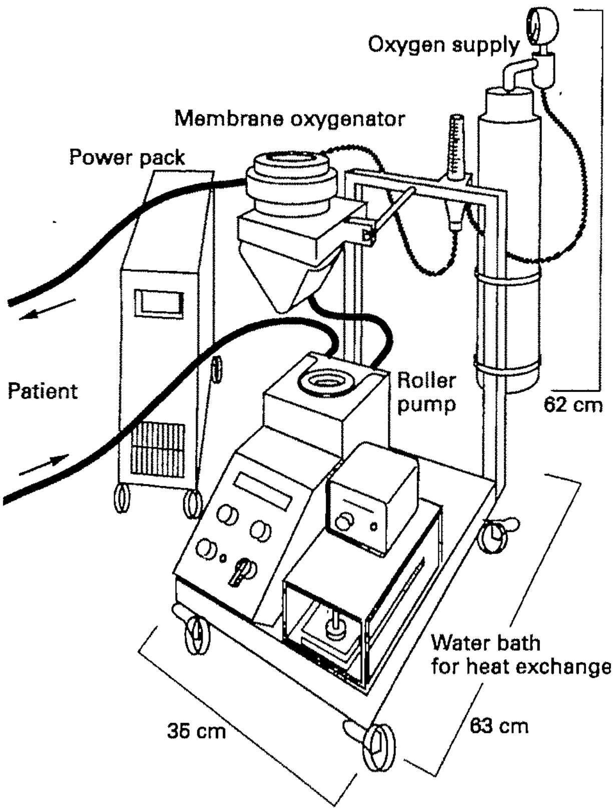

*Figure 2* Mobile ECMO with roller pump, membrane oxygenator, oxygen supply to ventilate the membrane lung, and water bath for heat exchanger. All electrical parts of the mobile ECMO are attached to an independent power pack.

the mobile ECMO unit were attached to a dedicated current powerpack (fig. 2).

The use of surface heparinized equipment reduced the need for heparinization. After an initial bolus injection of heparin 1000–2000 u. immediately before insertion of the cannulae, heparin was infused continuously to maintain the activated clotting time at 120–150 s.

After commencing ECMO, ventilator settings were adjusted for the decreased pulmonary gas exchange needs and to reduce further structural damage produced by high $F\text{I}_{O_2}$, large tidal volumes and/or high peak inspiratory pressures, that is patients' lungs were ventilated with a pressure controlled mode with a ventilatory frequency limited to $\leqslant 10$ bpm, I:E ratio of 1:1, peak inspiratory pressure $<35$ cm $H_2O$ and a PEEP of 9–16 cm $H_2O$. $F\text{I}_{O_2}$ was adjusted to maintain $Pa_{O_2}$ at 8–9.3 kPa. At this time inhaled nitric oxide, which was given to three patients by the referring physicians in order to improve arterial oxygenation,[13] was stopped. Infusions of cardiotonic or vasoactive drugs were continued if necessary, whereas parenteral nutrition was always stopped.

### TRANSPORT OF PATIENTS ON ECMO

After a stabilization period of 1–2 h, the patient was rearranged in the bed of the mobile ICU and connected to its monitor and respirator. The patient was then moved to the mobile ICU in which the patient, together with the ECMO unit, were placed on a loading ramp. The bed and mobile ECMO unit were anchored in the ICU bus. During inter-hospital transfer, ECG, systemic arterial, pulmonary arterial and central venous pressures, $Sp_{O_2}$ and temperature were monitored continuously. Blood-gas analyses were performed hourly.

On arrival at our hospital, a CT scan of the head and lungs was performed followed by measurement of systemic and pulmonary variables, in addition to arterial and mixed-venous blood-gas tensions. Oxygen contents of arterial, mixed venous and capillary blood were calculated and the venous admixture ($\dot{Q}va/\dot{Q}t$) was derived from the Berggren formula.[14] The quantity of extravascular lung water content (Lung Water Computer 9310, Edwards Laboratories, Irvine, CA, USA) was estimated using the double-indicator dilution technique.[15]

### STATISTICAL ANALYSIS

All data are presented as individual values or mean (SD). Differences between values before transport without ECMO and those after inter-hospital transfer with ECMO were analysed using the non-parametric Wilcoxon signed rank test. Changes were considered significant if $P<0.05$.

## Results

Eight patients with a $Pa_{O_2}/F\text{I}_{O_2}$ of 6.7 kPa at PEEP $\geqslant 5$ cm $H_2O$ for $>2$ h because of severe ARDS (Murray score 3.59 (0.23)) induced by multiple trauma or pneumonia were transferred on ECMO to our hospital. Before the start of ECMO, $Pa_{O_2}$ was 5.7 (0.5) kPa and $Pa_{CO_2}$ was 7.9 (1.5) measured at an $F\text{I}_{O_2}$ of 1.0, peak inspiratory pressure of 37.4 (6.1) cm $H_2O$ and PEEP of 12.6 (2) cm $H_2O$ (table 1). The interval between the request to transfer a patient and initiating ECMO was 513 (137) min. The 495 (123) km inter-hospital transport took 341 (151) min (table 2). The only complication related to transport which occurred was a breakage of a stop-cock on the top of the membrane lung during loading onto the bus. As the conus of the stop-cock remained in the membrane lung, the whole membrane lung had to be exchanged. However, the patient survived this event without adverse effects.

After arrival in our ICU, heart rate was 110 (26) beat $min^{-1}$, mean arterial pressure 83 (19) mm Hg, pulmonary artery pressure 29 (8) mm Hg and cardiac index 3.1 (0.3) litre $min^{-1}$ (table 3). Extravascular lung water was high with 33.4 (14.2) ml $kg^{-1}$. Comparing gas exchange variables and ventilator settings before transfer without ECMO with those after transfer with ECMO demonstrated that $Pa_{O_2}$ increased by 3.1 (0.9) kPa ($P=0.012$), and $Pa_{CO_2}$ decreased by 1.9 (1.4) kPa ($P=0.012$), $F\text{I}_{O_2}$ by 0.28 (0.18) ($P=0.028$), peak inspiratory pressure by 8.3 (7.4) cm $H_2O$ ($P=0.036$) and ventilatory frequency by 11.4 (3.4) bpm ($P=0.012$). Total duration of extracorporeal respiratory support was 8 (9) days.

Six patients survived and were discharged from hospital; two patients died as a result of multiple organ failure. In three of the six survivors we observed neurological symptoms after weaning from

*Table 1* Patients characteristics, gas exchange and ventilator settings at the first contact with the referring hospital. The severity of ARDS was determined as described by Murray and colleagues[10]; additional organ failures were determined using the score described by Goris and colleagues.[12] PIP=Peak inspiratory pressure, PEEP=positive end-expiratory pressure, $V_T$=tidal volume, $f$=ventilatory frequency

the ventilator which were thought to be caused by the hypoxia. All three patients recovered nearly completely during the following months.

## Discussion

Despite extensive research and increasing knowledge of the pathophysiology of ARDS, newer studies still show an overall mortality rate of more than 50% without ECMO.[16] In our centre, using a combination of advanced therapy and extracorporeal lung support as a last resort therapy the mortality rate was 27%.[17] However, until recently we refused patients who had a $Pa_{O_2}/F_{I_{O_2}}$ of 5.3 kPa in spite of optimization of ventilator settings, because we believed that these patients would not survive conventional inter-hospital transport. Furthermore, we were anxious to transfer patients with an $Pa_{O_2}/F_{I_{O_2}}$ of 5.5–6.7 kPa as in some of the latter patients transported before the onset of this study, gas exchange deteriorated further during inter-hospital transfer causing periods of arterial oxygen saturation of less than 65%. Boedy, Howell and Kanto reported a 12% mortality rate for transported infants before ECMO could be initiated.[18] For adults with severe ARDS, no data are available. Therefore, we developed a transport ECMO system to facilitate safe inter-hospital transport of patients with a $Pa_{O_2}/F_{I_{O_2}}$ of 6.7 kPa. This study has demonstrated that ECMO for transport of such patients was feasible with good results and no severe complications.

Some clinicians cast doubt on the benefit of extracorporeal lung support on survival in patients with severe ARDS, especially because two randomized, controlled studies failed to demonstrate an increase in survival using ECMO[11] or extracorporeal carbon dioxide removal.[19] The US ECMO study was conducted from 1974–1977 and published in 1979.[11] The results showed no differences in survival rates between patients treated by ECMO and patients undergoing mechanical ventilation alone. Patients treated with extracorporeal bypass and mechanical ventilation, and those treated with mechanical ventilation alone, had a high mortality rate (10% *vs* 8%). However, the ECMO regimen used in the US ECMO study differed markedly from the present method and, in our opinion, is not comparable. The main differences included the use of a high flow veno-arterial bypass potentially inducing insufficient oxygen supply to the lung, non-heparinized systems leading to severe bleeding complications, and mechanical ventilation with high airway pressures and high tidal volumes, possibly further damaging the lung. Moreover, the study was conducted during an influenza epidemic with a high frequency of pneumonia, a cause of ARDS known to be associated with a high mortality rate.[20] Furthermore, the poor results might also have resulted from the study design allowing termination of ECMO if after 5 days of treatment no improvement in lung function could be observed. However, it is well known today that initial improvement in lung function with subsequent survival may occur as late as day 10 to day 20 of treatment.

Similar shortcomings were observed in the second randomized, controlled study conducted from 1987 to 1991 in the pulmonary ICU of the University of Salt Lake City by Morris and colleagues.[19] The purpose of this study was to compare pressure-controlled inverse ratio ventilation (pcCMV-IRV) followed by low frequency positive pressure ventilation with extracorporeal carbon dioxide removal (LFPPV-$ECCO_2R$) with controlled positive pressure ventilation in patients with ARDS. Morris and colleagues found that survival was not significantly different in both groups (33% *vs* 42%), although overall survival rate had improved significantly compared with survival in the US ECMO study. A possible explanation for why Morris and colleagues could not show benefit from LFPPV-$ECCO_2R$ is that they reported 22 bleeding complications in the LFPPV-$ECCO_2R$-treated patients and had to terminate extracorporeal respiratory support in seven of 19 patients because of bleeding problems.[19] In contrast with our routine, Morris and colleagues used extracorporeal bypass with non-heparinized circuits and artificial lungs. The available literature suggests that bleeding remains the most common complication in adult patients with ARDS undergoing extracorporeal lung support, and seems to be related partly to constant heparinization.[8 21–24] Another explanation for the poor survival rates of Morris and colleagues in LFPPV-$ECCO_2R$- treated patients may be the relatively low extracorporeal blood flow rates of 2.38 (SEM 0.01) litre $min^{-1}$.[19] In order to accomplish a significant reduction in iatrogenic lung injury caused by mechanical ventilation, higher oxygen transfer rates would have been necessary, requiring a higher extracorporeal blood flow. In our patients extracorporeal blood flow was approximately 50% of cardiac output which makes limitation of peak inspiratory pressure to $\leq 36$ cm $H_2O$ and $V_T$s to $<10$ ml $kg^{-1}$ in our ECMO patients possible; Morris and colleagues had to apply a mean PIP of 49.5 cm $H_2O$ during the entire LFPPV-$ECCO_2R$ in order to maintain sufficient oxygenation.[19] In our opinion, after commencing pressure- and volume-limited ventilation combined with permissive hypercapnia, the main goal of extracorporeal lung support is to avoid irreversible hypoxic injury. This goal can be achieved using a veno-venous bypass technique with high extracorporeal blood flow and without causing bleeding complications, if heparin-coated systems are used.[9] Obviously, the technique itself cannot heal the lung but allows for sufficient arterial oxygenation in spite of less damaging ventilator settings, as demonstrated in our study. Finally, the extent of practical experience with extracorporeal lung support may also influence the results of clinical studies. Before the start of our study, we had treated more than 35 patients with ECMO, while Morris and colleagues had treated only two patients before they began their randomized clinical study. Although a further prospective, randomized study may be desirable, from our point of view, the positive results in Europe in more than 450 patients with severe ARDS clearly justifies the use of extracorporeal respiratory support as a last resort therapy.[25]

In particular, in the group of patients in this study with an assumed mortality risk of nearly 100%, inter-hospital transport could only be performed without the hazards of hypoxic injury by using ECMO, and six of eight patients survived. Our experience is in accord with that of other groups who consider ECMO to be a feasible alternative to conventional transport for hypoxic neonates or those with an unstable cardiopulmonary sysem,[26 27] or for adults.[28 29] However, to date, transport of patients receiving ECMO is not performed widely because of logistic or technical problems, or both. Using the described technical equipment (mobile ECMO, bed fitted with a ventilator, ICU bus) allowed us to perform all routine intensive care procedures with the exception of x-rays, and therefore this procedure is in accordance with the "Guidelines for the transfer of critically ill patients" provided by the American College of Critical Care Medicine.[30]

Using a ground transport facility for inter-hospital transport of patients led to a mean transfer time of 4.7 h. We are aware that air transport either with fixed-winged aircraft or with a helicopter would have shortened the duration of transport. However, we believe that in patients already receiving ECMO the duration of inter-hospital transfer is less important than adequate space for treatment and full availability of ICU equipment in the ICU bus. The time required for transportation in the ICU bus can be used for further optimization of ventilation and haemodynamic state.

An ECMO transport service is very costly in terms of personnel, vehicles and equipment. Such a service may deprive the ECMO centre of critical care staff for many hours. It would be preferable therefore to transport patients in need of advanced treatment of ARDS[17] at a time when the receiving hospital's ECMO entry criteria are not yet fulfilled. However, four of eight patients transported developed hypoxic respiratory failure and required mechanical ventilation within 2 days of the onset of the disease. Therefore, we believe that there is a need for safe facilities to perform such inter-hospital transport.

# Propofol anaesthesia and postoperative nausea and vomiting: quantitative systematic review of randomized controlled studies

M. TRAMÈR, A. MOORE AND H. MCQUAY

## Summary

We have analysed randomized controlled studies which reported the incidence of postoperative nausea and vomiting (PONV) after propofol anaesthesia compared with other anaesthetics (control). Cumulative data of early (0–6 h) and late (0–48 h) PONV were recorded as occurrence or non-occurrence of nausea or vomiting. Combined odds ratio and number-needed-to-treat were calculated for propofol as an induction or maintenance regimen, early or late outcomes, and different emetic events. This was performed for all control event rates and within a range of 20–60% control event rates. We analysed 84 studies involving 6069 patients. The effect of propofol on PONV was dependent mainly on the method of administration, time of measurement and range of control event rates. When all studies were included the number-needed-to-treat to prevent PONV with propofol was more than 9 when used for induction of anaesthesia and at best 6 when used for maintenance. Within the 20–60% control event rate range, best results were achieved with propofol maintenance to prevent early PONV: the number-needed-to-treat to prevent early nausea was 4.7 (95% confidence interval 3.8–6.3), vomiting 4.9 (4–6.1) and any emetic event 4.9 (3.7–7.1). Within the 20–60% control event rate, of five patients treated with propofol for maintenance of anaesthesia, one will not vomit or be nauseated in the immediate postoperative period who would otherwise have vomited or been nauseated. This may be clinically relevant. In all other situations the difference between propofol and control may have reached statistical significance but was of doubtful clinical relevance. Treatment efficacy should be established within a defined range of control event rates for meaningful estimates of efficacy and for comparisons. (*Br. J. Anaesth.* 1997; **78**: 247–255).

**Key words**
Anaesthetics i.v., propofol. Vomiting, nausea. Vomiting, antiemetics. Vomiting, incidence Statistics

Propofol is thought to be antiemetic and therefore useful to decrease the incidence of postoperative nausea and vomiting (PONV).[1–3] However, the mechanism of its effect on PONV is obscure. Interpretations range from propofol being less emetogenic than other anaesthetics[4] to being directly antiemetic.[2] When given in subanaesthetic doses after surgery either as prophylaxis[5 6] or as treatment,[2] results were contradictory.

A biological basis for propofol being an antiemetic is lacking. In animals, propofol did not interact strongly with dopamine D2 receptors[7] and in human volunteers subhypnotic doses of propofol did not prevent vomiting induced by the dopamine agonist apomorphine.[8] These data make it unlikely that propofol has a significant antiemetic effect via dopamine receptors.[9] Results from *in vitro* studies were inconclusive.[10 11] One *in vitro* model suggested that propofol had little or no effect on endogenous 5-$HT_3$ receptors while volatile anaesthetics enhanced 5-$HT_3$ receptor-mediated currents.[10] This may be indirect evidence that propofol has less emetogenic potency than other anaesthetics.[10] In another *in vitro* study propofol was shown to be a potent 5-$HT_3$ receptor blocker.[11] However, in this experiment all of the general anaesthetics examined caused concentration-dependent inhibition of the 5-$HT_3$ channel.[11] Other vague theoretical mechanisms of propofol and antiemesis include direct depressant action on the chemoreceptor trigger zone, vagal nuclei and other centres implicated in nausea and vomiting,[7] or modulation of some subcortical pathways.[2] Although documented anecdotally, propofol-induced improvement of mood and well-being could not be reproduced in a randomized experimental human study.[12]

The evidence is that propofol has only a minimal effect on vomiting in paediatric strabismus surgery, a clinical situation with a particularly high risk of PONV.[13] The aim of this meta-analysis was therefore to test the evidence that propofol, when used for induction or maintenance of anaesthesia, decreases the incidence of PONV compared with other anaesthetic techniques.

## Methods

MEDLINE (Knowledge Server v3.25) was searched (1981 to December 1995) for randomized

controlled studies which evaluated the effect of propofol compared with other anaesthetics (control) on PONV and reported the outcome in dichotomous form (number of patients with and without an outcome). The search strategy was not restricted to the English language and used combinations of the free text terms emesis, nausea, vomiting, adverse effects (subheading), and propofol, Disoprivan, Diprivan, Disopropofol or ICI35868. Additional reports were identified from reference lists of retrieved reports and from review articles of PONV and propofol. Unpublished studies were not sought. Abstracts were not considered. Reports without randomization or with an inadequate method of randomization (such as patient's date of birth) were excluded from analysis.

Information on patients, anaesthetics, surgery and definition of PONV was obtained from each report. Three different PONV outcomes were extracted in dichotomous form: nausea, vomiting (including retching), and any emetic event (nausea, vomiting or nausea and vomiting). These outcomes were treated separately as "emetic events". Incidences of early (0–6 h) and late (0–48 h) emetic events were extracted. Thus a maximum of three different emetic events could be extracted from each study, both early and late. When several incidences of events were reported at different times the cumulative values nearest to 6 and 48 h after operation were analysed. Emetic events "during recovery" or "after operation" were considered as early data. No weighting was used for different grades of nausea, number of vomiting episodes, time to first vomiting episode, number of patients needing antiemetic rescue medication, delay until discharge or scores of patient satisfaction.

When propofol was used only for induction it was compared with other i.v. or inhalation induction techniques. Propofol as a maintenance anaesthetic was compared with other maintenance regimens. When multiple comparisons were possible between propofol and several other anaesthetics in one study, only one control arm was analysed. The primary choice for control was, for induction, another i.v. agent and for maintenance, an inhalation method. Comparisons where propofol was used as an induction agent in both active and control groups were excluded. Comparisons between a nitrous oxide-free propofol arm (total i.v. anaesthesia) and a nitrous oxide-based control arm were not considered because of the potential effect of nitrous oxide on emesis.[14] However, studies were analysed when nitrous oxide was omitted in both the propofol and control arms.

The plot of L'Abbé, Detsky and O'Rourke[15] of event rates with propofol compared with control event rates was used as a graphical means of exploring the efficacy of propofol and homogeneity of the data set. A scatter predominantly lying between the line of equality and the control axis suggested efficacy with propofol and homogeneity.

Statistical significance and clinical relevance of the efficacy of propofol were evaluated using odds ratio and number-needed-to-treat (NNT)[16] methods. Odds ratio estimates were calculated with 95% confidence intervals (95% CI) using a fixed effects model.[17] Point estimates and 95% CI of the NNT were calculated.[18] The NNT indicated how many patients had to be exposed to propofol in order to prevent one particular emetic event in one of them, who would have had this emetic outcome with a control treatment (that is, with another anaesthetic).

Efficacy was defined as absence of an emetic event. The efficacy of propofol was analysed separately for different modes of administration (induction, maintenance), different times (early, late emetic events) and different emetic events (nausea, retching/vomiting, any emetic event). This was done by combining single propofol or control arms both independent of control event rates (i.e. for all incidences of emetic events with control anaesthetics) and within a range of 20–60% control event rates (i.e. after exclusion of all data from studies with a control event rate less than 20% or greater than 60%). This range of control event rates was a *post hoc* definition.

Absence of a statistically significant improvement of propofol over control was assumed when the lower 95% confidence limit of the odds ratio was <1 or when the NNT point estimate was either negative or its upper 95% confidence limit included no effect (an infinite NNT). For simplification, only NNT with 95% CI are shown. Our arbitrary definition of a clinically relevant effect for prophylaxis of PONV was an NNT ≤5. An NNT of 5 would be the best estimate of efficacy which could be achieved with a control event rate of 20%.

Calculations were performed using Excel v 4.0 on a Power Macintosh 7100/66. Tables with data extracted from the analysed reports, including odds ratios with confidence limits, are available from the world-wide-web (http://www.jr2.ox.ac.uk/Bandolier/painres/propponv.html).

## Results

We considered 122 reports for analysis; 19 were excluded because propofol was used for induction in the control group (11 studies) and/or because nitrous oxide was omitted in the propofol but not in the control group (eight studies) and no other comparisons were possible. Another 19 studies were excluded for various reasons; six were not randomized,[19–24] the randomization method was inadequate in four,[25–28] the technique of maintenance was not mentioned in two,[29 30] three were not adequately controlled (opioid or droperidol only in one group),[31–33] one had eltanolone as the only control arm[34] and data from three studies were published twice.[35–40]

Data from 84 randomized controlled studies involving 6069 patients (3098 treated with propofol) were analysed. A list of these references is given in the appendix. Median group size was 22 (range 10–75) patients. Thirty-one (37%) studies were sponsored by the manufacturer of propofol. Propofol as an induction agent or as a maintenance regimen was compared with other anaesthetic techniques in a large variety of surgical settings in children and adults. Maintenance of anaesthesia with propofol included induction with propofol or an initial bolus of propofol in all studies.

*Table 1* One control arm per emetic outcome and study. Nausea, vomiting (including retching), and any emetic event (nausea, vomiting, or nausea and vomiting) may be reported in one study. *(a) and (c)=number of patients in whom the event was absent; (b) and (d)=the total number of patients in the listed studies. Control event rate=Incidence of emetic outcomes in control group; CI=confidence interval; n/a=not applicable. Early events=0–6 h; late events=0–48 h; ∞=infinity (negative value, indicating absence of a statistically significant difference between propofol and control). Odds ratios with 95% confidence limits are available from the internet (http://www.jr2.ox.ac.uk/Bandolier/painres/propponv.html)

The event rate scatters (fig. 1) suggested improvement with propofol over control mainly for early outcomes when propofol was used for maintenance, and also suggested homogeneity for all data sets. The mean control event rate (incidence of PONV in controls) was 22% (range 0% to almost 70%). For all 84 randomized controlled studies a total of 169 different control event rates (nausea, vomiting or any emetic event) were reported; 77 (46% of all reported events) had an incidence less than 20% and six (4%) an incidence of more than 60%.

### COMBINED ANALYSIS FOR ALL CONTROL EVENT RATES (TABLE 1)

For all control event rates the combined analysis indicated statistically significant results (NNT confidence interval excluding infinity) in favour of propofol for all three PONV outcomes only when propofol was used as a maintenance regimen and only when early events were analysed. Under these conditions, 11–16% of patients (NNT 6.2 for absence of any emetic event, 8 for absence of nausea and 9.2 for absence of vomiting) undergoing propofol anaesthesia will not have an emetic event in the early postoperative period, who would have vomited or been nauseated with another anaesthetic.

When early and late outcomes after propofol as an induction agent or late outcomes after propofol maintenance were analysed, the combined NNT for all control event rates was always greater than 9 and, except for late absence of nausea after propofol maintenance, sometimes propofol was not significantly different from control.

### ANALYSIS WITHIN THE RANGE OF 20–60% CONTROL EVENT RATES (TABLE 1, FIG. 1)

Within the 20–60% range of control event rates, the mean incidence of early and late PONV in controls

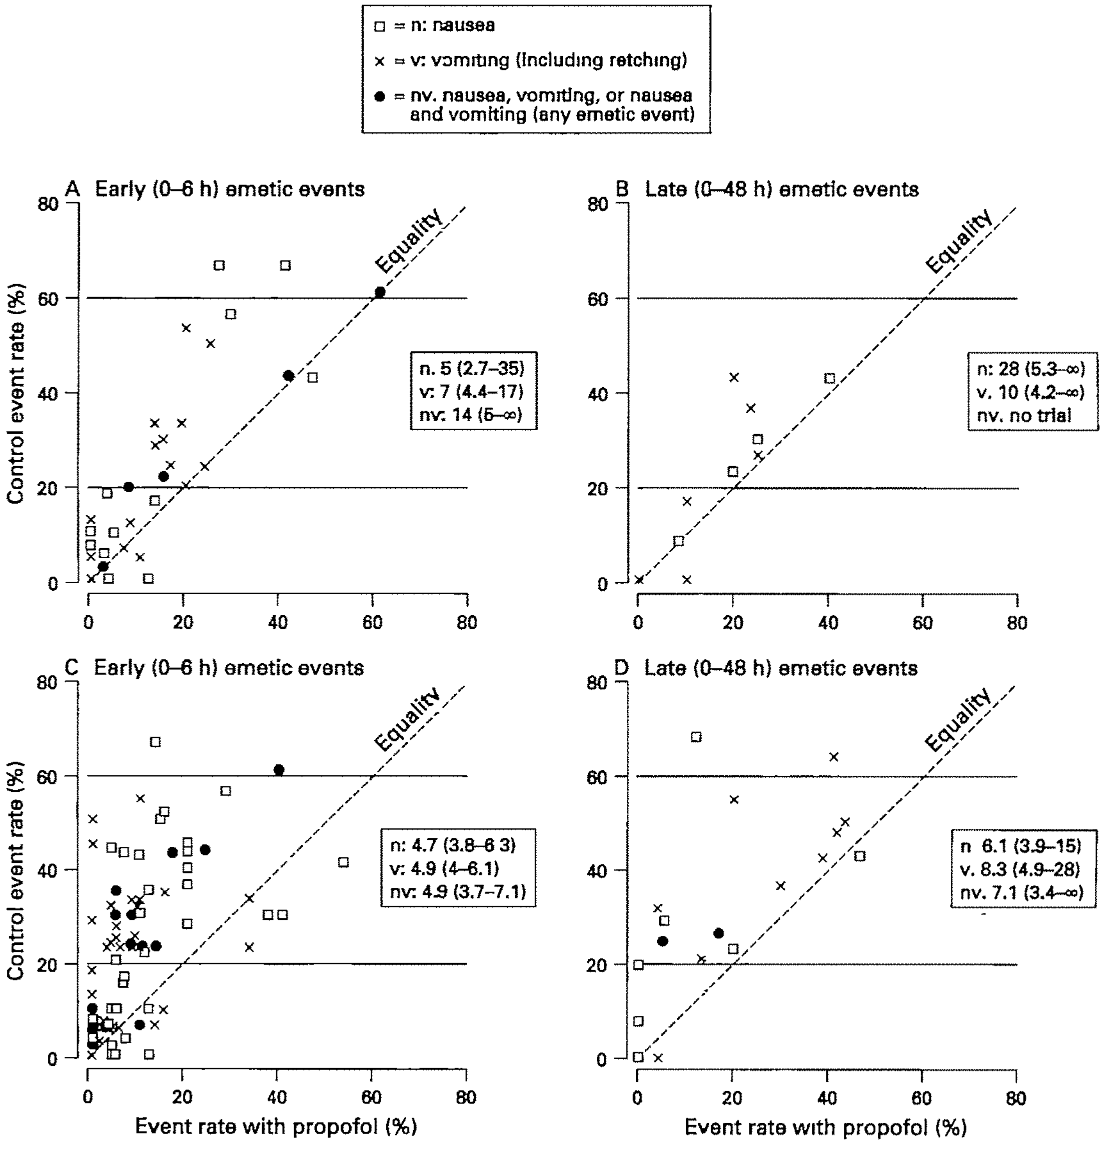

*Figure 1* Early (A, C) and late (B, D) emetic event rates with propofol for induction (A, B) and maintenance (C, D) of anaesthesia compared with other anaesthetics (control). Three different emetic events (see key), both early and late, may be from one study. Only one control arm per study is considered. Horizontal lines indicate a range of control event rates of 20–60%. Values are number-needed-to-treat (95% confidence interval) to prevent an emetic event with propofol within this range. ∞=infinity (absence of a statistically significant difference between propofol and control).

was 36% and 32% when propofol was used for induction, and 33% for both times when propofol was used for maintenance.

Propofol induction (fig. 1A, B) was significantly better than control for absence of both early nausea and vomiting (NNT 5 and 6.7, respectively, each with wide confidence intervals). Absence of any emetic event in the early postoperative period after propofol induction was not significantly different from control. Late outcomes after propofol induction were either not significantly different from control or there were no studies reporting this outcome.

Propofol as a maintenance regimen (fig. 1C, D) was significantly better than control for all early emetic events; point estimates of the NNT to prevent early nausea, vomiting and any emetic event were approximately 5, with confidence intervals ranging from 4 to 7. Prevention of late vomiting and nausea with a propofol maintenance regimen had an NNT of approximately 8 and 6, respectively, both with wide confidence intervals, whereas prevention of late combined emetic events was not significantly different from control.

### SUBGROUP ANALYSIS: TWO DIFFERENT SURGICAL SETTINGS

In 11 studies, propofol maintenance was compared with other anaesthetics in more than 1000 patients undergoing minor gynaecological surgery (abortion, curettage).[41–51] The mean incidence of early vomiting without propofol was 10%; the NNT to prevent early vomiting with propofol was 16 (11–32).

In five studies of 200 patients undergoing major gynaecological surgery, including hysterectomy and laparoscopy,[52–56] the mean incidence of early vomiting in controls was 32%; the NNT to prevent early vomiting with a propofol maintenance regimen compared with other anaesthetics was 4.2 (3–8).

## Discussion

Two of the most recent comprehensive review articles on propofol stated that a significant decrease in PONV was observed with the use of propofol for anaesthesia,[57] and that an increasing body of literature supported the antiemetic activity of propofol.[3] However, very few review articles use valid methods to identify, assess and synthesize information.[58]

The main steps in our approach to propofol and PONV were to identify data systematically and without bias, to define homogeneous subgroups of clinical interest and to use quantitative methods of analysis which allowed sensible statistical and clinical conclusions to be drawn. Further, an arbitrary range of control event rates, excluding studies with very low or very high PONV incidences, enabled analysis of treatment efficacy within a set of data from studies with clinical validity. The lower boundary (control event rate 20%) was set because antiemetic prophylaxis was not considered to be worthwhile when the event rate without treatment was less than 20%. Moreover, in such a setting there would not be enough nausea or vomiting to allow sensitive assay of treatment efficacy. The upper boundary (control event rate 60%) was set because a study which reported an incidence of nausea or vomiting in controls of more than 60% could not be considered as representative of clinical routine. Although a high incidence of vomiting may be reported in particular settings, such as paediatric strabismus surgery,[13] this cannot be regarded as a representative cross-section of clinical reality. Audit has shown that the mean incidence of nausea and vomiting across different surgical settings is approximately 20–40%.[59–62] When control event rates extend beyond this any intervention may become more or less effective and confound the combined results of a meta-analysis.

Within the 20–60% range, mean PONV incidences in controls were similar for early and late outcomes, and for propofol as an induction agent and maintenance regimen. Comparisons of efficacy could, therefore, be made between forms of administration (induction *vs* maintenance) and times (early *vs* late outcomes) without the danger of confounding the results because of different levels of control event rates.

What are the clinically relevant results of this meta-analysis? First, propofol anaesthesia should not be regarded as a universal prophylactic antiemetic if used non-selectively; too many patients would have to be treated with propofol in order to prevent PONV in one of them. A large number of studies and patients in a great variety of clinical settings were analysed; the risk of emetic outcomes without propofol when all studies were included was approximately 22%. This indicates that the data set was a representative cross-section of clinical routine rather than a selected subgroup of high-risk settings. Combined analyses for this data set, regardless of the control event rates, showed a clinically negligible effect of propofol on PONV compared with controls (number-needed-to-treat >5) and sometimes the difference was not statistically significant. These results suggest that it may be inappropriate to expect a beneficial effect of propofol on PONV in every clinical situation.

Second, within the restricted range of control event rates (20–60%) propofol may decrease the incidence of PONV to a clinically relevant extent, but only when given as a maintenance regimen and only in the first few hours after surgery. Even in this setting five patients have to be treated with propofol to prevent early nausea or vomiting in one of them, who would have vomited or been nauseated with another anaesthetic. For late PONV this degree of benefit was lost; despite the same mean control event rate, point estimates of the NNT were higher than for early outcomes and confidence intervals were wide or included no benefit. These results suggest that propofol, when used for maintenance of anaesthesia, may produce a short-lived 20% reduction in vomiting and nauseated patients in a high-risk setting for emesis (i.e. control event rate 20–60%). These results also suggest that the effect of propofol on PONV does not influence long-term patient comfort. It is interesting to note in this connection that late emetic outcomes, although of undoubted importance,[63] were documented in only approximately

25–30% as many patients as early outcomes. This may be because of several factors. Anaesthetists may not be interested in late outcomes and may avoid the increased effort which is needed for prolonged follow-up of patients.

Third, although there is no way from our model to predict an individual patient's outcome with propofol, it may be possible to identify clinical subgroups with higher event rates and a corresponding greater efficacy with propofol. This was shown for paediatric strabismus surgery[13] and confirmed in this study, because women undergoing major gynaecological interventions were much more likely to profit from the effect of propofol on PONV than those undergoing minor gynaecological surgery. Subgroup analysis may enable more rational decision making on how and when to use propofol in a particular group of patients to optimize any potential effect on PONV. This subgroup analysis also demonstrated that it is possible to identify clinical settings where a beneficial effect of propofol on PONV is unlikely.

Fourth, although suggested recently,[64] propofol as an induction agent cannot be regarded as worthwhile prophylaxis for PONV. The efficacy of propofol was either inconsistent or clinically irrelevant for early outcomes and not significantly different from control for late outcomes.

In conclusion, based on data from all published randomized, controlled studies there is evidence that propofol may have a clinically relevant effect on PONV, but only in the short term, when given as a maintenance regimen and when the event rate without prophylaxis is more than 20%. In all other situations—propofol for induction, late outcomes, low control event rates—the difference between propofol and control may be statistically significant but is clinically unimportant. It is over optimistic to expect propofol to act as an antiemetic in every clinical setting, especially if the event rate without prophylaxis is low.

# Meta-analytic comparison of prophylactic antiemetic efficacy for postoperative nausea and vomiting: propofol anaesthesia *vs* omitting nitrous oxide *vs* total i.v. anaesthesia with propofol

M. TRAMÈR, A. MOORE AND H. MCQUAY

## Summary

Data from two published and one new meta-analysis were reviewed to compare the antiemetic efficacy of three different anaesthetic regimens: (i) propofol anaesthesia compared with another anaesthetic (control); (ii) anaesthesia without nitrous oxide compared with the same anaesthetic with nitrous oxide (control); (iii) propofol anaesthesia without nitrous oxide (TIVA) compared with another anaesthetic with nitrous oxide (control). Efficacy (prevention of postoperative nausea and vomiting compared with control) was estimated using odds ratio and number-needed-to-treat methods, and compared within a range of 20–60% control event rates for early efficacy (0–6 h) and 40–80% for late efficacy (0–48 h). Propofol anaesthesia or omitting nitrous oxide had similar effects on vomiting, both early and late. Propofol (but not omitting nitrous oxide) decreased the incidence of nausea. TIVA studies were documented poorly; appropriate comparisons with other interventions were not possible. Efficacy of treatments should be compared within a setting-specific range of control event rates. There is insufficient evidence that TIVA with propofol is an anaesthetic technique with a low emetogenic potency. (*Br. J. Anaesth.* 1997; **78**: 256–259).

**Key words**
Anaesthetics i.v., propofol. Vomiting, nausea. Vomiting, antiemetics. Vomiting, incidence. Statistics. Anaesthetics gases, nitrous oxide.

Many pharmacological interventions for preventing postoperative nausea and vomiting (PONV) have been discussed over the past 30 yr.[1–6] The relative efficacy of these interventions is documented poorly and there is no "gold standard". This gold standard would be the most efficacious and least harmful, and increasingly, the cheapest intervention.[7]

In comparing the efficacy of different antiemetic interventions (as opposed to comparing one intervention with a control[8 9]), a new reason for a limited range of control event rates arises. If the efficacy of intervention A has been tested mainly in studies with high control event rates, and intervention B in studies with low control event rates, then intervention A will have more scope for improvement over its control. Therefore, the efficacy of A relative to B would be overestimated.

The choice of upper and lower limits of a restricted band of control event rates for comparing antiemetic efficacy is arbitrary. It should create a band as narrow as possible to reduce the risk of confounding comparisons of estimates of efficacy and should take into account the most likely distribution of event rates without interventions. The compromise is to achieve homogeneity of data but not to exclude too many studies. For this study, both an increased risk of PONV in populations selected for antiemetic studies (and therefore an increased likelihood for high control event rates) and an increase in the cumulative incidence of PONV over time (early *vs* late outcomes) were taken into account.

We defined an appropriate range of control event rates for PONV in which to compare the antiemetic efficacy of three different anaesthetic interventions: propofol maintenance, omitting nitrous oxide and total i.v. anaesthesia (TIVA) with propofol (that is propofol anaesthesia without nitrous oxide).

## Methods

Relevant data were from three separate sources: directly from a published meta-analysis comparing propofol maintenance (intervention) with another anaesthetic (control)[8]; a reworking of a published meta-analysis of anaesthetics without nitrous oxide (intervention) compared with the same anaesthetic but with nitrous oxide (control)[9]; and a new meta-analysis of randomized, controlled studies comparing the antiemetic efficacy of TIVA with propofol (intervention) with another anaesthetic with nitrous oxide (control). Studies for this latter meta-analysis were sought using the same strategy and criteria as previously for the propofol studies (see accompanying article).[8]

For each data set of an intervention the procedure (systematic search of randomized, controlled studies, extraction of PONV data) was essentially the

MARTIN TRAMÈR, MD, ANDREW MOORE, DPHIL, HENRY MCQUAY, DM, Pain Research, Nuffield Department of Anaesthetics, The Churchill, Oxford Radcliffe Hospital, Headington, Oxford OX3 7LJ. Accepted for publication: November 18, 1996.

Correspondence to: M. T.

same as described previously.[8 9] Three different PONV outcomes were extracted in dichotomous form (i.e. presence or absence of PONV): nausea, vomiting (including retching) and any emetic event (nausea or vomiting). This was done for two time periods: 0–6 h (early PONV) and 0–48 h (late PONV).

Only estimates of efficacy of studies with an early control event rate between 20 and 60% or a late control event rate between 40 and 80% were analysed and compared with each other. These PONV comparator ranges for early and late outcomes were *post hoc* definitions. The early comparator range (20–60% control event rate) was taken from another meta-analysis.[8] The late comparator range (40–80% control event rate) was judged appropriate for the increased late control event rates found in antiemetic studies (unpublished data). Because of the difference between the two ranges, there was no intention to compare early antiemetic efficacy with late antiemetic efficacy.

Statistical significance and clinical relevance of efficacy were evaluated as described in the accompanying article.[8] The main estimate of efficacy was the number-needed-to-treat, which indicated how many patients had to be exposed to an intervention in order to prevent one particular emetic event (nausea, retching/vomiting or any emetic event) in one of them, who would have had this emetic event with the corresponding control treatment.

A statistically significant improvement of an intervention over control was assumed when the upper limit of the 95% confidence interval (CI) of the number-needed-to-treat did not include a negative value (infinity). A significant improvement of one intervention over another intervention was assumed when the 95% CI of the NNT did not overlap, although this is a notably conservative assumption.

Calculations were performed using Excel v 4.0 on a Power Macintosh 7100/66. Tables with data extracted from the analysed reports, including odds ratios with confidence limits, are available from the world-wide-web (http://www.jr2.ox.ac.uk/Bandolier/painres/propponv.html).

## Results

A comparison between TIVA with propofol and a non-propofol–nitrous oxide anaesthetic was found in nine studies[10–18]; in only four were the control event rates within the defined ranges, either early or late.[11 13–15] In all TIVA comparisons the control arm included induction with thiopentone and a maintenance regimen with nitrous oxide and isoflurane, enflurane or halothane.

Relevant data for the two other interventions, propofol maintenance and omitting nitrous oxide, were from a reworking of two previous meta-analyses.[8 9]

### EARLY OUTCOMES (FIG. 1)

The scatter of event rates suggested efficacy in preventing early emetic events with all interventions, especially TIVA.

When data were analysed within the early comparator range (control event rates 20–60%) both propofol for maintenance and omitting nitrous oxide had a similar effect on early vomiting compared with the corresponding control intervention (number-needed-to-treat point estimate approximately 5). Propofol maintenance was as good at preventing early nausea or any emetic event (nausea or vomiting), whereas omitting nitrous oxide was not significantly different from control in preventing early nausea, and prevention of any emetic event was not documented within the comparator range.

Prevention of early vomiting with TIVA showed a tendency for greater efficacy than propofol maintenance or omitting nitrous oxide. However, there were insufficient relevant data with TIVA to allow meaningful comparisons with the other interventions. The analysable TIVA data set within the comparator range was based on 66 treated patients from three small studies reporting vomiting as an early outcome.[11 13 15] The 95% confidence limits of the number-needed-to-treat to prevent early vomiting of all three interventions overlapped. Prevention of early nausea with TIVA, reported within the comparator range in only one study,[14] was not different from propofol maintenance.

### LATE OUTCOMES (FIG. 1)

For all three interventions there was little indication of late efficacy (to 48 h) from the event rate scatters.

Within the late comparator range (control event rates 40–80%) propofol for maintenance and omitting nitrous oxide had the same, statistically significant effect on vomiting. Propofol maintenance showed a favourable effect on late nausea (number-needed-to-treat point estimate approximately 3) but using data from only 38 patients from two small studies with contradictory results. Omitting nitrous oxide had no effect on late nausea. With both interventions prevention of any late emetic event (nausea, vomiting, or nausea and vomiting) was either not significantly different from control (omitting nitrous oxide) or not documented (propofol).

Within the late comparator range, only one TIVA study reported prevention of vomiting as an outcome[15]; late efficacy was not significantly different from a halogenated–nitrous oxide anaesthetic in 25 treated patients.

## Discussion

Quantitative analysis of combined data extracted from systematically searched randomized controlled studies is a powerful test of the evidence that an intervention is efficacious and was used here to try to improve our poor understanding of the relative potency of antiemetic interventions.

Antiemetic efficacy may be identified in a high-risk or low-risk setting. This inequality may confound comparisons between treatments and underlines the necessity of using only studies with comparable underlying risk. Because risk is not well understood in PONV studies we have to rely on the event rate in controls who did not receive an antiemetic treatment. Indeed, we have to assume that there is a close

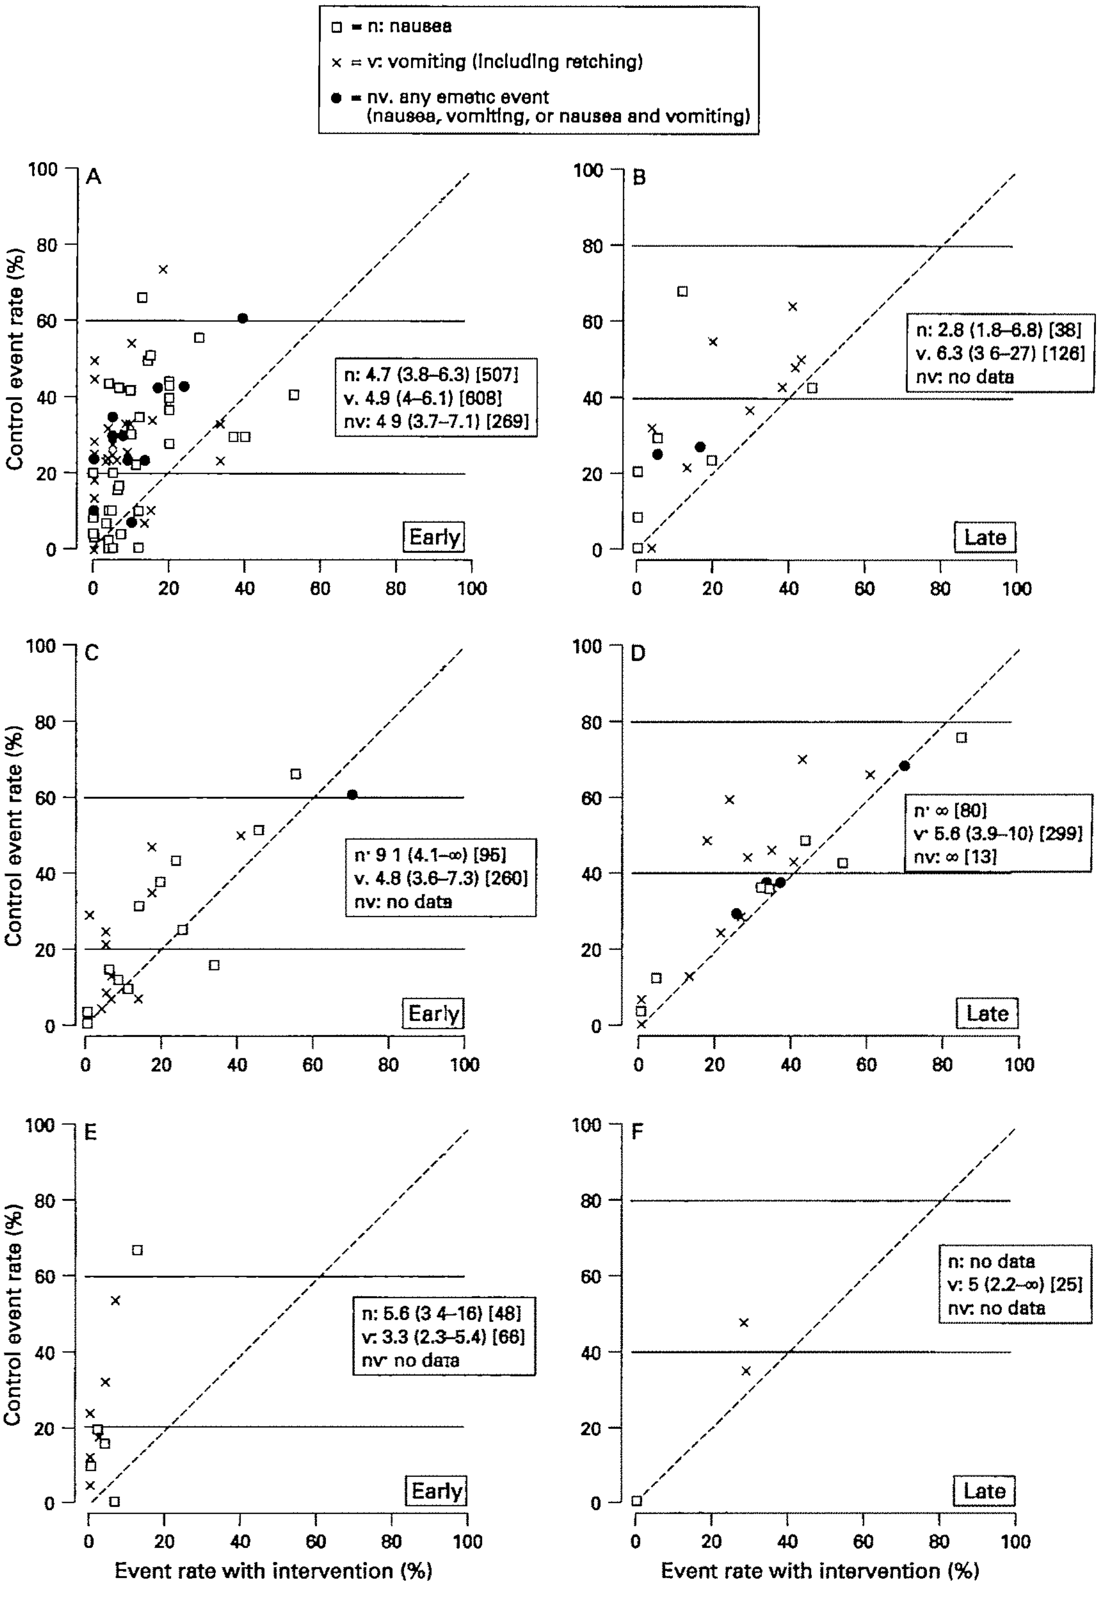

*Figure 1* Early (0–6 h) and late (0–48 h) emetic event rates with: A, B: propofol maintenance (control=another anaesthetic); C, D: omitting nitrous oxide (control=same anaesthetic with nitrous oxide); E, F: total i.v. anaesthesia (control=another anaesthetic with nitrous oxide). Symbols are comparisons between an intervention and control. One study may report 1–3 different emetic events (see key), both early and late. Horizontal lines indicate early (20–60%) and late (40–80%) control event rate comparator ranges. Values are number-needed-to-treat (95% confidence interval) [numbers of treated patients] to prevent an outcome with an intervention compared with control within the comparator range. ∞=Infinity.

relationship between underlying risk and this control event rate and, therefore, we use control event rate as an indicator of risk. We have defined a PONV comparator range of control event rates to evaluate the effect of propofol, as an induction agent or as a maintenance regimen, on early and late PONV.[8] In that study the logic was to eliminate those studies which had little opportunity to show an improvement and those that were clinically irrelevant. In this study the aim was to create a narrow band of control event rates which represented outcomes of the majority of antiemetic studies. Interventions may then be compared on the same basis.

What are the clinically relevant results of this study?

A propofol maintenance anaesthetic and omitting nitrous oxide in general anaesthesia had approximately the same effect on early and late postoperative vomiting. Our model was not designed to compare early with late antiemetic efficacy as in another meta-analysis.[8] However, these results suggest that, even in settings with an extraordinarily high risk of nausea and vomiting (i.e. 40–80% incidence of PONV without prophylaxis), approximately six patients have to be treated with either method to prevent long-term vomiting in one of them. The number-needed-to-treat confidence limits suggested that this number could be twice as high when nitrous oxide is omitted and almost five times as high when propofol is used. Such antiemetic long-term efficacy cannot be regarded as clinically relevant.

Omitting nitrous oxide had no effect on early nausea whereas propofol decreased the incidence of early nausea to the same extent as early vomiting. Prevention of late nausea with propofol maintenance suggested a favourable effect, but from only a few treated patients in two small studies with contradictory results.

Because of the very few studies in the PONV comparator range, TIVA with propofol cannot be recommended based on the present evidence. Even if subsequent studies provided enough data to show a statistically significant and clinically relevant advantage over the two other techniques, there is still the factor that nitrous oxide with propofol reduces the risk of intraoperative awareness[9] and eventually decreases cost.[19 20]

# A model of the electrocortical effects of general anaesthesia

J. W. SLEIGH AND D. C. GALLETLY

## Summary

In an attempt to describe how reduction in synaptic efficiency by general anaesthetic agents results in loss of consciousness, we examined the behaviour of a two-dimensional (a lattice of 80×80 cellular elements) cellular automaton (CA) computer model as the connectivity between cellular elements was altered. The lattice was taken to represent cortical elements with variable connectivity to their neighbours. The summation of the active elements of the CA lattice was taken to represent a simulated "EEG" signal. If cellular automaton elements had a high probability of connectivity, the simulated EEG showed high frequency predominance and low amplitudes, similar to the desynchronized pattern in an alert person. As connectivity was decreased, median frequency in the simulated EEG decreased and amplitude increased, similar to that in anaesthetized patients. As in our model, we believe it is possible that the human central nervous system in the conscious resting state exists above a critical threshold of synaptic efficiency; awareness is associated with an increase in synaptic efficiency and anaesthesia with a decrease that sharply reduces cortical information transfer. (*Br. J. Anaesth.* 1997; **78**: 260–263).

**Key words**
Anaesthesia, general. Theories of anaesthetic action. Model, computer.

Attempts to explain the mechanisms of action of general anaesthetic agents have concentrated primarily on their effects at the cellular or molecular level.[1–3] In order to understand the mechanisms by which general anaesthetics produce unconsciousness however, it is necessary to link these neurophysiological actions with the resulting disruption that occurs in symbolic information processing or consciousness. In this article we attempt to provide a simple model of cortical EEG activity which illustrates how subtle changes at the neuronal level may result in major and sudden transitions in the global behaviour of the cerebral cortex.

It is unlikely that general anaesthetic action is related to a specific brain site as anaesthesia is a general phenomenon occurring in all life forms to some degree. Similarly, it seems unlikely that general anaesthesia is related to a specific neural effect as it is a property of a wide range of different chemical compounds. Therefore, it is probable that anaesthesia is the final common pathway for a relatively non-specific brain effect.

In recent years, several studies have narrowed down the putative site of action of general anaesthetics.[4] Although the exact mechanisms remain unclear, the perceptual phenomenon of "loss of consciousness" appears closely linked to disruption of cortical association activity.[2] This has been seen electrophysiologically as a decrease in amplitude and an increase in latency in the mid- and long-latency auditory and somatosensory evoked cortical potentials.[5] These appear to be consistent findings that are largely independent of the anaesthetic agent used.[6] Evoked potential studies clearly demonstrate the resistance to anaesthetic action of brain stem processing, relative to that of the cerebral cortex.[7]

Many physical systems are composed of collections of interacting subsystems. The functional output of the whole system at a "macroscopic" level depends almost totally on how these "microscopic" component parts interact. In this field of study a large body of literature has developed that describes how the overall behaviour of a system may change in response to changes in the interactions between the subsystems. It has been observed that dramatic changes (termed phase transitions) at the macroscopic level may occur at certain "critical points" at the microscopic level. A common example of phase transition is the change of a polymer from a sol to a gel form such as happens when cooking an egg. Alterations in the communication or "connectivity" between the individual microscopic elements (the protein molecules) causes a major change in the structure and behaviour of the collective macroscopic system (the egg).

Can we attempt to apply this phase transition model to the phenomenon of general anaesthesia? We suggest that a phase transition resulting in failure of accurate information transmission between spatially separated neuronal assemblies is at least in part an explanation for loss of consciousness. This relatively abrupt phase transition in information transmission is largely concealed behind the relatively continuous smooth changes of EEG

frequency and amplitude that occur with increasing depth of anaesthesia.

In this article we describe a simple two-dimensional "cellular automaton" model that displays a surprising similarity in behaviour to that of the cerebral cortex, as measured by EEG changes during anaesthesia. The model is similar to the two-dimensional lattice that has been used to describe phase transitions in both the physical sciences[8–10] and ventricular fibrillation in the heart.[11]

## COMPUTER MODEL

A computer program was written in the C language to simulate an 80×80 lattice of units, each of which communicates with its four neighbours (fig. 1). Each unit is capable of passing information or activating its neighbours with a certain probability (the "bond linkage probability" (Pb)). The overall output of the system is defined as the number of active units. This model is similar to the well known "forest fire" model used for describing activity in random resistor networks, polymer bonds and epidemics.[8–10]

The assumptions which relate this model to that of the effects of anaesthetics on cortical function are: (a) it is probable that the cerebral cortex is divided into functional units, each approximately 0.1 $mm^3$ in size.[12] Thus our 80×80 lattice can be thought of as analogous to a two-dimensional surface of cerebral cortex where each unit represents a functional neuronal subsystem; (b) the voltage of the EEG signal is the result of summation of postsynaptic potentials.[13] This might be represented in the model as the total number of active or "depolarized" units in the lattice at any specified time; (c) a major mechanism of action of anaesthetics at the cellular level is to disturb synaptic efficiency in some way.[14] This could be mimicked by a reduction in the probability (Pb) of each unit depolarizing its neighbour. By adjusting values of Pb we could examine the hypothetical effect of a drug which altered synaptic efficiency.

The simulations were implemented on a 40-MHz 486 processor-based microcomputer running under MSDOS, each run lasting approximately 2–5 min.

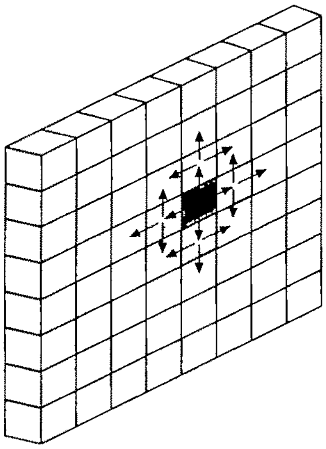

*Figure 1* Visual representation of the spread of activity in the cellular automaton model. Pb is the probability that each cell in the lattice communicates with its neighbour in the direction shown by one of the arrows.

At regular intervals of one time step, an excitatory depolarizing input signal was applied to a random element on one side of the lattice. At each subsequent time step the neighbouring elements became depolarized according to a predefined probability Pb from 0 to 1. Each depolarized site then became refractory to excitation for one time step. This resulted in a wave of activity passing through the lattice. The time taken for the wave to traverse the lattice is known as the percolation time. A short percolation time indicates relatively unimpeded information transfer across the lattice. Conversely, a long percolation time suggests poor information transfer. After an initial period of 500 time steps to reach a steady state, the resultant activity, the "voltage", within the lattice was recorded over time (1000 time steps). We examined this activity over a range of values for Pb. A second simulation was performed in which the excitatory input signal was applied to the empty lattice only when the preceding wave had died out or had reached the opposite side of the lattice. From this simulation 40 percolation times were calculated for each level of Pb. The percentage of percolation times less than 120 time steps (=1.5 lattice size) was chosen arbitrarily as an estimate of the efficiency of information transfer across the lattice and termed the "percolation time index" (PTI).

## PATIENT DATA

For comparative purposes we obtained EEG traces from five, healthy consenting male patients undergoing general anaesthesia for minor surgical procedures. Anaesthesia was induced in each patient with propofol 2–2.5 mg $kg^{-1}$ and fentanyl 100–200 μg, and maintained with 1% isoflurane and 66% nitrous oxide in oxygen. Neuromuscular block was produced with vecuronium as required. Five minutes before induction of anaesthesia and during unstimulated anaesthesia, 30-s epochs of EEG data were recorded from a right occipito-temporal electrode (O2-T4: 10–20 international system). The EEG signal was filtered (low pass 0.3 Hz, high pass 100 Hz), amplified (Grass P511K) and digitized at a sampling rate of 500 Hz using a 14-bit ADC data acquisition unit (Strobes APC, Wellington, NZ). Electrode impedance was less than 5 kΩ. The digitized waveform was transferred to a microcomputer.

These true EEG values were compared with "pseudo EEG data" obtained from the computer simulation with regard to their spectral characteristics.

## Results

Allowing for the relatively small size of the lattice, its observed collective behaviour was similar to results obtained for physical phase transitions.[8]

Data from patients during general anaesthesia showed the well described and expected shifts towards the lower frequencies with induction of anaesthesia; increased power in the delta and theta bands, diminished power in the alpha and beta

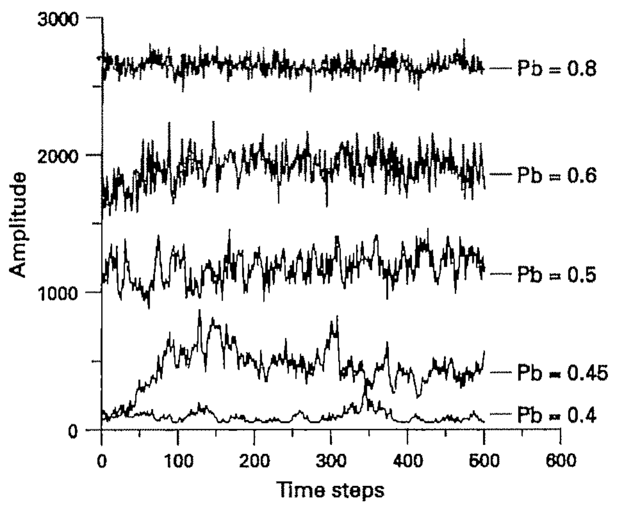

*Figure 2* Typical examples of simulated EEG output from the computer model at various different Pb values. The vertical axis shows absolute amplitude, as measured by the number of active elements at each time step. The horizontal axis is time steps. Unlike true EEG, the signal has not been filtered and therefore represents both AC and DC components.

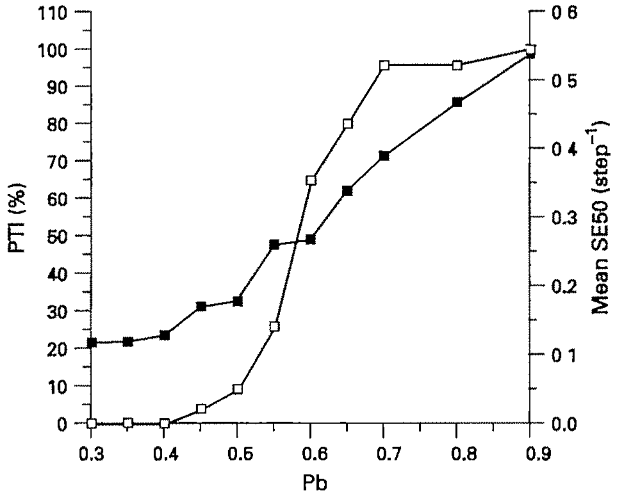

*Figure 3* Mean SE50 (■) and percolation time index (PTI) (□) *vs* Pb values. The SD of the SE50 values was small and relatively constant, ranging from 0.01 to 0.02.

bands and a decrease in spectral edge 50% (SE50).

Activity of the lattice is shown for different Pb values in figure 2. For high (0.8) Pb values (i.e. there was a high probability of a unit depolarizing its neighbouring elements), we observed a low amplitude, high frequency predominance in the power spectrum. As Pb approached the critical value of 0.5, we observed increasing amplitude and lower frequency spectral predominance similar to the EEG data obtained from anaesthetized patients. Below a Pb value of approximately 0.4, forms of intermittency phenomena started to occur with increasing periods of electrical silence interspersed with high amplitude waves. As Pb approached 0.3 the "pseudo EEG" became almost totally silent.

Figure 3 shows the mean SE50 and PTI for the simulations as Pb values were adjusted. The SE50 values are the mean of 10 simulations at each level of Pb. The characteristic feature of SE50 decreasing in a relatively smooth linear manner with decreasing Pb values was similar to the known effects of general anaesthesia.[15] In contrast, cortical information transmission, as estimated by PTI, changed markedly as the critical point was approached. Above the critical point, lattice activity tended to be self-sustaining, whereas below the threshold almost all of the signals rapidly died out.

## Discussion

Attempting to understand how the nervous system processes information without detailed knowledge of specific neural interactions might appear to be an overambitious goal. It is possible, however, that detailed knowledge of the immense complexity of neuronal activity and interactions may not be necessary to understand the essential features of anaesthesia and consciousness.

The activity of our simple cellular automaton model was surprisingly similar to that described for the EEG effects of general anaesthesia. Increasing low frequency activity and reduction of spectral edge occurred smoothly throughout a range of bond linkage probabilities.

The crucial point of the phase transition model is that it relates the abstract notion of information transfer to some measurable output of the system, in this case EEG voltage. Thus when amplitude and wavelength in an EEG increase, it suggests that the rate of information transfer around the cortex has been slowed greatly (fig. 3). Theoretically, as Pb decreases to 0.5, the time for an impulse to traverse the lattice increases rapidly, becoming infinite when Pb <0.5.[8] As a corollary, the best EEG index of awareness is likely to be one that most closely follows the state of information transfer. The SE50, being almost linearly related to Pb, is not very sensitive in this regard and measures that include correlation and time information may be better.

Although the cellular automaton model of phase transition is very general and has been applied to a wide range of different problems, it is consistent with, and complements, a large body of work that suggests that in a state of calm resting, association activity within the cerebral cortex functions above a critical phase transition. Thus cognition of an olfactory input suddenly changes chaotic olfactory cortical activity into regular activity and meaningful behaviour becomes associated with temporal and spatial coherence of the brain's magnetic field.[16 17] It is probable that in the unstimulated state, the complex chaotic dynamics of the central nervous system provides the brain with rich "random" patterns of behaviour from which new adaptive patterns emerge and gives the brain a "flexibility" to respond to external stimuli. The process of arousal, as evidenced by desynchronization of the EEG signal, is thought to be mediated by improved connectivity between neuronal subsystems[12 18 19] just as in our cellular automaton model, which showed that increasing Pb resulted in a less deeply anaesthetized EEG pattern. While anaesthesia may reduce connectivity (i.e. reduced Pb) there is evidence that the profound stimulation of surgery acts to reverse this disconnecting effect.[20 21]

Part of the difficulties with using power spectral EEG analysis to estimate awareness during general anaesthesia is that, for intermediate ranges, the SE50 does not reliably differentiate between awake and unaware patients. It is possible that these subjects are close to the steep part of the phase transition curve (i.e. Pb was close to its critical value). Thus small variation within the population or over time in a single individual results in large changes in cortical information processing (awareness or anaesthesia).

This example demonstrates an important phenomenon associated with phase transitions, that is that the same stimulus can produce completely different effects depending on whether the system is near or far from a critical transition point. This may in part explain conflicting research results which are common in the biological literature.

In summary, we believe that the cellular automaton model provides a useful basis for interpretation of electroencephalographic changes associated with general anaesthesia. Further elaboration of this model may help our understanding of the phenomena of consciousness.

# Role of vasopressin in the haemodynamic response to laparoscopic cholecystectomy

A. D. WALDER AND A. R. AITKENHEAD

## Summary

We studied 10 patients undergoing laparoscopic cholecystectomy (group 1) and five control patients (group 2). We measured heart rate, arterial pressure, right atrial pressure (RAP), cardiac index (CI), systemic vascular resistance index (SVRI), intrathoracic pressure (ITP), plasma osmolality, adrenaline, noradrenaline and arginine vasopressin (aVP) concentrations, and serum renin activity (SRA), and calculated the atrial transmural pressure gradient (ATPG). We recorded significant decreases in mean arterial pressure (MAP), SVRI and CI in both groups ($P<0.05$) after induction of anaesthesia. MAP and SVRI increased ($P<0.01$) while CI decreased further in group 1 patients during the pneumoperitoneum. In group 1 plasma aVP concentration increased after insufflation of the pneumoperitoneum to a level sufficient to cause the recorded haemodynamic changes. ATPG decreased in group 1 patients during the pneumoperitoneum, and this is a recognized trigger for aVP release. (*Br. J. Anaesth.* 1997; **78**: 264–266).

**Key words**
Surgery, laparoscopy. Hormones, vasopressin. Cardiovascular system, effects.

A large increase in mean arterial pressure (MAP) associated with an increase in systemic vascular resistance index (SVRI) and a reduction in cardiac index (CI) is observed in patients undergoing laparoscopic cholecystectomy.[1–4] This occurs despite the head-up position and increased intra-abdominal pressure which would be expected to decrease venous return of blood to the heart and reduce CI, with a consequent reduction in MAP or its maintenance by a compensatory increase in SVRI. The observed increases in MAP and SVRI are much greater than would be expected from a compensatory response to a reduction in CI, and this infers a direct effect on SVRI. An increase in plasma arginine vasopressin concentration (aVP) has been shown to occur in patients undergoing gynaecological laparoscopy with carbon dioxide pneumoperitoneum,[5 6] and the magnitude of this response is haemodynamically significant.[7] This study was designed to assess the relationship between haemodynamic changes during laparoscopic cholecystectomy and plasma concentrations of aVP.

## Patients and methods

The study was approved by the local Ethics Committee and informed consent was obtained from 18 ASA group I or II patients; 13 were undergoing laparoscopic cholecystectomy (group 1) and five were undergoing minor limb procedures (group 2=control). Inclusion criteria were body weight not more than 20% over ideal weight and no cardiorespiratory disease or medications. All patients received temazepam premedication.

General anaesthesia was induced with propofol 2–3 mg $kg^{-1}$ and maintained with 1–2% isoflurane and 66% nitrous oxide in oxygen. Alfentanil 10 μg $kg^{-1}$ was given before tracheal intubation which was facilitated with vecuronium 0.1 mg $kg^{-1}$. Morphine 0.1 mg $kg^{-1}$ was given for analgesia. Hartmann's solution was infused at 5 ml $kg^{-1}$ $h^{-1}$. Ventilation of the lungs was adjusted to maintain a constant end-tidal carbon dioxide partial pressure of 4.0–4.5 kPa.

Head-up tilt of 15° was set after 10 min (both groups). Pneumoperitoneum was induced in group 1 patients after another 10 min. The carbon dioxide pneumoperitoneum was maintained at 14 mm Hg by an automatic insufflator throughout the laparoscopic procedure.

At the end of surgery residual neuromuscular block was antagonized with neostigmine given with glycopyrronium.

Arterial pressure was measured every 3 min using a Dinamap 1846SX. CI and heart rate were recorded continuously (measured by thoracic electrical bioimpedance using the BoMed NCCOM3-R7 (BoMed Medical Manufacturing Ltd, Irvine, CA, USA)) and averaged over 16 beats. The method used to derive cardiac output has been described previously.[8] Right atrial pressure (RAP) was measured every 5 min after insertion of a central venous catheter after induction. Intrathoracic pressure was measured with a three-channel pressure transducer (Gaeltec CT/G/S3-1, Gaeltec, Dunvegan, Isle of Skye, Scotland) placed in the

oesophagus 5 cm proximal to the lower oesophageal sphincter and atrial transmural pressure gradient (ATPG) calculated as RAP−ITP. The positions of the CVP and oesophageal catheters were confirmed radiologically using an image intensifier. SVRI was calculated as 80 (MAP−RAP)/CI.

Blood samples were obtained before induction of anaesthesia (T0), 5 min after induction of anaesthesia (T1), 5 min after head-up positioning (T2), 5 min after induction of pneumoperitoneum (T3), after 30 min of pneumoperitoneum (T4) and 5 min after desufflation (T5). In the control group, T3 and T4 were taken as 15 min and 45 min after head-up positioning, respectively, and T5 as 5 min after the end of surgery. Some of the blood from T0, T3 and T5 was analysed for osmolality. All other samples were placed on ice and centrifuged in a refrigerated centrifuge, and the plasma then stored at −40 °C for later analysis for adrenaline, noradrenaline and aVP concentrations, and serum renin activity. Catecholamine concentrations were assayed by high pressure liquid chromatography, and renin activity and aVP by radioimmunoassay.

Differences in the results were assessed using the two sample *t* test with $P<0.05$ considered significantly different.

## Results

Mean ages and weights of the patients were 51 (range 42–63) yr and 72 (SEM 3) kg, respectively, in group 1 and 47 (33–58) yr and 70 (5) kg in group 2. There were five male patients in group 1 and four in group 2.

Three patients were converted from laparoscopic to open cholecystectomy after 18, 22 and 25 min of pneumoperitoneum, respectively, because of technical surgical difficulties. Data from these patients were excluded from analysis.

Changes in haemodynamic variables are shown in tables 1 and 2. There was a significant decrease in MAP, CI and SVRI in both groups of patients after induction of anaesthesia. A significant increase in MAP and SVRI, associated with a further decrease in CI, occurred in group 1 patients after insufflation of the peritoneum. These changes were maintained throughout the duration of the pneumoperitoneum and returned to normal after desufflation. Right

atrial pressure (RAP) and intrathoracic pressure (ITP) increased in group 1 patients during the pneumoperitoneum, ITP more so than RAP. ATPG decreased during the pneumoperitoneum.

Plasma noradrenaline and adrenaline concentrations, renin activity and serum osmolality did not change significantly in either group.

Plasma aVP concentration did not change significantly during surgery in group 2 patients. In group 1, plasma aVP concentration did not change after induction but increased markedly after insufflation of the peritoneum and remained high after 30 min, decreasing rapidly after desufflation (tables 3, 4).

## Discussion

We found no significant changes in plasma concentrations of adrenaline and noradrenaline, or plasma renin activity in either group of patients. We selected patients undergoing minor peripheral surgery as controls so that the stress response to surgery, and its effects on haemodynamic state, would be minimal and there would be no stimuli from handling or stretching of intra-abdominal viscera.

The reduction in CI and increases in MAP and SVRI have been shown previously in both laparoscopic cholecystectomy and gynaecological laparoscopy.[1–4 9–11] An increase in SVRI with an unchanged or slightly reduced MAP might be expected in patients in the head-up position with increased intra-abdominal pressure as a response to decreased CI secondary to decreased venous return of blood to the heart. The observed increase in SVRI, however, was far greater than would be appropriate for a compensatory mechanism. This suggests that the increase in SVRI is triggered directly, rather than being a feature of compensatory adjustments to other cardiovascular changes.

The marked increase in plasma aVP concentration in patients undergoing laparoscopic cholecystectomy occurred immediately after the pneumoperitoneum was formed and reduced soon after the pneumoperitoneum was released. This temporal relationship and the very high concentrations of aVP recorded have been noted previously in patients undergoing laparoscopy under local anaesthesia.[12]

Release of aVP has been shown to occur in response to an increase in osmolarity, but the maximal response to this stimulus is at a plasma aVP concentration of approximately 10–20 pmol $\text{litre}^{-1}$.[7] Osmolality did not change significantly throughout the study in any of our patients.

The plasma concentrations of aVP in group 1 patients during the pneumoperitoneum have been shown to be associated with significant cardiovascular effects in humans.[7] The typical response to plasma aVP concentrations in excess of 30 pmol $\text{litre}^{-1}$ is increased SVRI and MAP with a decrease in CI.[7] The timing of aVP release in group 1 patients and its magnitude are consistent with a causative action to increase SVRI and MAP and reduce CI.

Traction on abdominal viscera is known to stimulate aVP release,[13] but traction on abdominal viscera during laparoscopic cholecystectomy is not very great. In addition, the plasma aVP concentration increased within 5 min of insufflation with carbon dioxide, but before manipulation of the gallbladder had started.

Decreasing the transmural atrial pressure gradient (more negative intra-atrial pressure or more positive intra-thoracic pressure) has been shown to result in a rapid increase in plasma aVP concentration.[12 14 15] The timing and degree of change in ATPG we recorded were consistent with a triggering action of ATPG on the release of aVP.

In summary, we have shown a marked increase in plasma aVP concentration during pneumoperitoneum in patients undergoing laparoscopic cholecystectomy. The scale of the increase in aVP concentration and its timing are consistent with a causal relationship with recorded increases in SVRI and MAP, and decrease in CI. The observed decrease in ATPG is a likely trigger for aVP release.

# Pharmacodynamics and pharmacokinetics of rocuronium in intensive care patients†

H. J. SPARR, J. M. K. H. WIERDA, J. H. PROOST, C. KELLER AND K. S. KHUENL-BRADY

**Summary**

We have studied dose requirements, recovery times and pharmacokinetics of rocuronium in 32 intensive care patients. After an initial dose of 50 mg, rocuronium was administered as maintenance doses of 25 mg whenever two responses to train-of-four (TOF) stimulation reappeared (bolus group; $n$=27) or by continuous infusion to maintain one response in the TOF (infusion group; $n$=5). Median requirements for rocuronium were 27.4 (range 14.5–68.3) mg $h^{-1}$ and 43.7 (30.9–50.3) mg $h^{-1}$ in patients in the bolus and infusion groups, respectively. Median total duration of rocuronium administration was 29.0 (12.4–95.5) h and 63.4 (24.0–140.3) h, respectively. Median time from administration of the last bolus dose and end of infusion to recovery of the fourth twitch in the TOF was 100 (45–300) min and 60 (15–155) min, respectively. Arterial blood samples were obtained for up to 10 h after cessation of rocuronium administration, and concentrations of the parent compound and its putative metabolites were measured using high pressure liquid chromatography (HPLC). The plasma concentration profile ($n$=12) was described adequately by a two-compartment model. Mean plasma clearance ($Cl$), steady-state distribution volume ($V^{ss}$), mean residence time (MRT) and elimination half-life ($T_{1/2}{}^{\beta}$) were 3.16 (SD 1.15) ml $kg^{-1}$ $min^{-1}$, 769 (334) ml $kg^{-1}$, 262 (120) min and 337 (163) min, respectively. Recovery times, $V^{ss}$, MRT, and $T_{1/2}{}^{\beta}$ differed from previously published data obtained after rocuronium infusion of moderate duration in surgical patients. (*Br. J. Anaesth.* 1997; **78**: 267–273).

**Key words**
Neuromuscular block, rocuronium. Pharmacodynamics. Pharmacokinetics, rocuronium. Intensive care.

Rocuronium (Org 9426) is a new aminosteroidal, non-depolarizing neuromuscular blocking agent which has an intermediate time course of action and is related chemically to vecuronium (2-morpholino, 3-desacetyl, 16-N-allylpyrrolidino derivative). Several maintenance doses of rocuronium did not result in an increase in duration of action.[1] In surgical patients the pharmacokinetics of rocuronium given as a single bolus dose followed by a continuous infusion have been shown to be similar to those obtained after a single bolus dose.[2–4] The main route of elimination of rocuronium appears to be the hepatobiliary pathway and, unlike vecuronium, rocuronium does not appear to be metabolized in the liver.[5] This may be an advantage of rocuronium in comparison with vecuronium, which has a pharmacologically active 3-OH metabolite. This metabolite is thought to contribute to cumulative characteristics of vecuronium after usual clinical doses given to healthy volunteers[6] and after long-term administration in critically ill patients with concomitant renal failure.[7]

Neuromuscular blocking agents are used occasionally to facilitate mechanical ventilation in intensive care patients, although their use has declined over the past 5 yr,[8] partly because a growing number of reports on delayed recovery from neuromuscular block have appeared.[9 10] One important factor contributing to prolonged neuromuscular block may be absolute and relative overdoses of the neuromuscular blocking agent, which may be attributable to the lack of regular monitoring of the patient's neuromuscular function during drug administration.[11]

This first study of rocuronium in intensive care patients aimed to determine the dose of rocuronium required to facilitate smooth mechanical ventilation in conditions of adequate analgesia and sedation and to ascertain recovery time and pharmacokinetics.

## Patients and methods

We studied 32 patients admitted to the intensive care unit (ICU) because of acute respiratory failure, or multiple trauma or blunt brain trauma, or both, necessitating mechanical ventilation for an anticipated

†Presented in part at the 5th International Neuromuscular Meeting, Tokyo, November 1994, and at the Rocuronium Investigators' Meeting, Luxembourg, January 1995

period of at least 24 h. After approval by the Ethics Committee of the Medical Faculty at the University of Innsbruck, written informed consent was obtained from the patients' closest relatives or, whenever this was impossible, from the attending intensivist who was not involved in the study. Exclusion criteria were known alcohol or drug abuse, severe hepatic, renal or cardiac disease, neuromuscular disease, pregnancy, age less than 18 or more than 70 yr on admission, and administration of vecuronium within 4 h before the study. On admission, an acute physiological and chronic health evaluation (APACHE) II score and, if applicable, an injury severity score (ISS) were calculated.

In all patients analgesia and sedation were provided by continuous infusion of sufentanil 0.3–1.8 $\mu g\ kg^{-1}\ h^{-1}$ or fentanyl 2–12 $\mu g\ kg^{-1}\ h^{-1}$ and midazolam 0.2–0.8 $mg\ kg^{-1}\ h^{-1}$ to maintain the patient comfortable and free of agitation at any time. Combined parenteral and enteral nutritional support was standardized and included carbohydrates (up to 4 $g\ kg^{-1}\ day^{-1}$), amino acids (up to 2 $g\ kg^{-1}\ day^{-1}$) and lipids (up to 2 $g\ kg^{-1}\ day^{-1}$). Depending on the predisposing disease, other drugs were administered concurrently (i.e. dopamine, dobutamine, phenylephrine, adrenaline, noradrenaline, nitroglycerin, amrinone, frusemide, ranitidine and sucralfate, and antibiotics (ß-lactam antibiotics, aminoglycosides, ciprofloxacin, metronidazole, polymyxin, sulbactam and vancomycin)).

A range of laboratory values, including tests of liver function and calculated creatinine clearance, were obtained daily. Haemodynamic, pulmonary gas exchange and other variables were monitored as part of routine clinical management and were not evaluated further in this study.

### MODES OF ROCURONIUM ADMINISTRATION

Rocuronium was administered i.v. as an initial bolus dose of 50 mg. In 27 of 32 patients (bolus group) neuromuscular block was maintained with repeat doses of rocuronium 25 mg given each time the second response in the indirectly evoked train-of-four (TOF) was detectable by tactile or visual assessment (i.e. approximately 80% neuromuscular block).[12] In the remaining five patients (infusion group) continuous infusion of rocuronium was started at an initial rate of 0.25 $mg\ kg^{-1}\ h^{-1}$ at the time of recovery of the first response in the TOF (T1) after the initial bolus dose. The infusion rate was then adjusted to maintain T1 (i.e. approximately 95% neuromuscular block).[12]

### NEUROMUSCULAR MONITORING

Using a constant-current nerve stimulator (Digistim, Neuro Technology Inc, Houston, TX, USA) in the TOF mode, the ulnar nerve was stimulated at the wrist every 15 min. The number of visual and tactile responses of the thumb was recorded by trained medical students throughout administration of the drug. After cessation of administration of the neuromuscular blocking agent, the time from the last bolus dose and the end of rocuronium infusion, respectively, to the reappearance of all four twitches in the TOF mode was recorded. In addition, in 15 patients the time to attain a TOF ratio of 0.7 was determined by a new neuromuscular transmission monitor based on accelerometry (TOF Guard, Biometer, Denmark), as this device became available in the course of this study.

### PHARMACOKINETICS

In 16 of 32 patients (11 in the bolus group and five in the infusion group) plasma concentrations of rocuronium and its putative metabolites were measured in arterial blood samples. A blank blood sample was obtained either before the first bolus dose or at least 3 days after cessation of rocuronium administration, preferably before the patient was discharged from the ICU. In patients in the bolus group blood samples were obtained approximately every 6 h, just before a repeat dose was administered. In patients receiving rocuronium by continuous infusion, blood samples were obtained at 2, 4, 7, 12, 20, 40 and 60 min after administration of the bolus dose and just before and 1 h after the start of infusion. Furthermore, before and 1 h after a change in the infusion rate, additional samples were obtained. After the last repeat dose, or after cessation of the infusion, samples were obtained at 5, 10, 20, 40, 60, 90, 150, 240, 360, 480 and 600 min. Blood was collected in lithium-heparinized tubes. Plasma was separated within 240 min after withdrawal. Sodium dihydrogen phosphate ($NaH_2PO_4$ 1 mol $litre^{-1}$) solution was added to plasma (0.2 ml of acid to each 1.0 ml of plasma). Samples were stored at −18 °C until analysis.

Concentrations of rocuronium and its potential metabolites, 17-desacetyl-rocuronium (Org 9943) and 16-*N*-desallyl-rocuronium (Org 20860), were measured using high pressure liquid chromatography (HPLC) with 3,17-didesacetyl vecuronium as the internal standard. The precision (reproducibility) of the method was 8% over the range 10–100 000 ng $ml^{-1}$ for rocuronium, 7% over 10–25 000 ng $ml^{-1}$ for 17-desacetyl rocuronium and 12% over 10–25 000 ng $ml^{-1}$ for desallyl rocuronium. The lower limits of detection were 3, 5 and 15 ng for rocuronium, 17-desacetyl rocuronium and desallyl rocuronium, respectively.[13]

The plasma concentration–time data were analysed using the program MultiFit (JH Proost, University Centre for Pharmacy, Groningen, The Netherlands). This program has been used in several pharmacokinetic studies with rocuronium.[2–4] The parameters of a two- and three-exponential function were fitted to the logarithm of the measured plasma concentration, assuming a constant relative error and using the Marquardt algorithm for minimization of the residual sum of squares.[14] Initial estimates of the parameters were obtained from the plasma concentration–time data after the last bolus dose or after the end of the last infusion period. The fitting procedure took into account each plasma concentration measurement and each rocuronium bolus dose administration and, for the infusion group, dose rate, time of start and time of change of each subsequent rocuronium infusion. To test if a three-exponential function fitted better to the data than a two-exponential function, the $F$ test was applied.[15] The volume of the central compartment ($V^c$), steady-state volume of distribution ($V^{ss}$), plasma clearance ($Cl$) and mean residence time (MRT) were calculated using standard equations,[16] assuming that elimination takes place from the central compartment.

STATISTICAL ANALYSIS

Descriptive statistics were applied to patient data, dose requirement for rocuronium, total dose of rocuronium administered, duration of treatment, neuromuscular and kinetic variables. The data were summarized by means of sample size, median, mean (SD), minimum and maximum values. For each patient the mean amount of rocuronium administered per hour was calculated separately. Linear regression analysis was applied to recovery times *vs* duration of treatment, total dose of rocuronium administered, creatinine clearance and tests of liver function (aminotransferases, bilirubin), respectively.

## Results

The 32 intensive care patients (30 males) were given a median APACHE II score of 18 (range 11–39). Median age, weight and height of these patients were 29 (16–65) yr, 80 (60–105) kg and 180 (165–195) cm. Twenty-seven of 32 patients were trauma patients with a median injury severity score (ISS) of 30 (5–59); the remaining five were non-trauma patients. Median creatinine clearance was 110.5 (27.0–186.0) ml min$^{-1}$. Median values for alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities were 22.0 (5–78) iu litre$^{-1}$ and 30.0 (5–93) iu litre$^{-1}$, respectively, and median total bilirubin concentration was 25.1 (3.9–194.4) µmol litre$^{-1}$. Conditions precipitating admission to the intensive care unit are summarized in table 1. Twenty-five of the 32 patients recovered from their illness and were discharged from the ICU at 2–40 days after admission. Of the seven patients (22%) who died because of the severity of their illness, four died within 1 week after administration of rocuronium had been stopped and three died 2–7 weeks later.

*Table 1* Summary of conditions precipitating admission to the ICU. ALI=acute lung injury, ARDS=acute respiratory distress syndrome

| No. of patients | Cause of admission (associated conditions) |
|---|---|
| Trauma patients | |
| 12 | Head trauma + multiple trauma |
| 8 | Multiple trauma |
| 7 | Head trauma |
| Non-trauma patients | |
| 3 | ALI or ARDS (pneumonia, HIV infection; acute necrotizing pancreatitis; empyema of pleura, sepsis) |
| 2 | Acute respiratory failure (heart failure intraoperatively; chronic lung disease) |

PHARMACODYNAMICS

### *Dose requirements, total dose and duration of treatment*

In the 27 patients in the bolus group the median dose of rocuronium required to maintain approximately 80% neuromuscular block was 27.4 (median 14.5–68.3) mg h$^{-1}$ and 0.34 (0.18–0.85) mg kg$^{-1}$ h$^{-1}$, respectively. Median duration of treatment was 29.0 (12.4–95.5) h, and the total dose of rocuronium administered was 875 (375–5775) mg. Evaluation of the amount of rocuronium administered per hour to individual patients revealed a significant time effect, which was investigated further. Dose requirements of rocuronium per hour were fitted to a model using weighted non-linear regression in order to compensate for the decrease with time in the number of patients treated. The dose requirement *vs* time relationship is described by the following equation: mean dose (t)= $0.3793\times 0.5314\times e^{(-0{,}755\times t)}$. From this equation it can be calculated that the mean amount of rocuronium needed for neuromuscular block decreases from 0.63 to 0.38 mg kg$^{-1}$ h$^{-1}$ during the first 6–9 h and remains constant thereafter (fig. 1).

In the five patients in the infusion group one response to TOF (i.e. approximately 95% neuromuscular block) was maintained by a median rocuronium dose of 43.7 (range 30.9–50.3) mg h$^{-1}$ and 0.54 (0.52–0.63) mg kg$^{-1}$ h$^{-1}$, respectively. In this group of patients median duration of treatment was 63.4 (24.0–140.3) h and the total dose administered was 2014 (965–7051) mg. Because of the relatively small number of patients in the infusion group no attempt was made to analyse dose requirements over time as was done in the bolus group.

### *Recovery of neuromuscular function*

Recovery data could not be obtained from all patients because some required further neuromuscular block (with vecuronium or pipecuronium) after the study period. The speed of recovery is summarized in table 2. The total dose of rocuronium administered, duration of treatment (fig. 2) and creatinine clearance and tests of liver function (ALT,

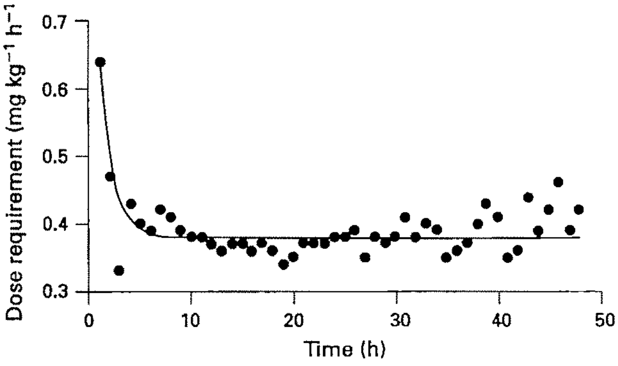

*Figure 1* Mean dose of rocuronium (●) administered to patients in the bolus group ($n$=27) during the first 48 h and estimated relationship between dose and time (represented by the solid line).

*Table 2* Summary of recovery characteristics after administration of the last bolus dose of rocuronium and after cessation of rocuronium infusion, respectively (median (range)). Time to T4=Time until presence of fourth response in TOF; time from T1 to T4=time between reappearance of the first and fourth response in TOF; time from T4 to TOF 0.7=time between reappearance of the fourth response to TOF and attainment of T4/T1 ratio of 0.7. | Time from T1 to T4 (min) | 19 | 50 (30–145) | 5 | 60 (15–155) |
| Time from T4 to TOF 0.7 (min) | 10 | 115 (40–220) | 5 | 125 (75–440) |

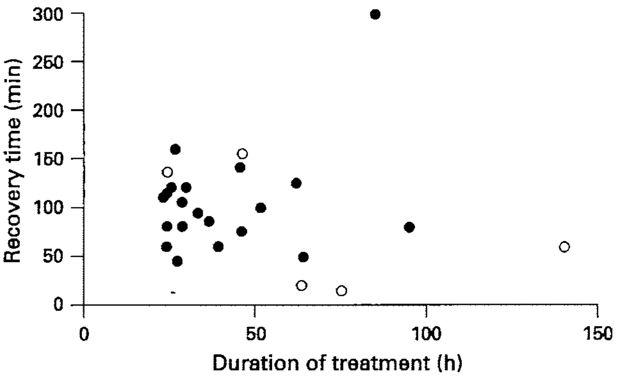

*Figure 2* Recovery time, that is time to reappearance of the fourth response in the TOF after the last bolus dose (●) or the end of infusion (○) *vs* duration of treatment.

AST, bilirubin) did not reveal any significant correlation with time to recovery of T4 (i.e. four responses of the thumb to TOF stimulation) after the end of rocuronium administration. In 15 patients recovery of the T4/T1 ratio was obtained. In these patients mean plasma concentration of rocuronium at a TOF ratio of 0.7 was 870 (SD 460) [range 430–1830] μg litre$^{-1}$.

PHARMACOKINETICS

Plasma samples of 16 patients were available for pharmacokinetic analysis. Four of these patients could not be included in the summary statistics of pharmacokinetic variables because of insufficient sampling (one patient) or unreliable estimates of the calculated variable because of a large residual coefficient of variation. In the final analysis the outcome of the two-exponential fit was preferred. In this study, the mean residual coefficient of variation (cv) was 16% (range 10–26%), which is not markedly higher than the measurement error in the rocuronium plasma concentration assay (10–15%). In general, standard errors of estimated individual pharmacokinetic variables were relatively small; the mean value of the relative standard error was 5 (range 2–17) % for clearance, 28 (8–66) % for $V^c$, 14 (7–38) % for $V^{ss}$, 11 (5–23) % for MRT and 19 (5–38) % for terminal half-life. The main pharmacokinetic variables in the bolus ($n$=8) and infusion ($n$=4) groups are summarized in table 3 together with data from two previous studies in surgical patients where rocuronium was administered as a single bolus dose followed by continuous infusion to maintain 90% neuromuscular block for a period of approximately 2 h.[2 3]

## Discussion

Knowledge of pharmacodynamics and pharmacokinetics of neuromuscular blocking agents acquired in the course of studies in surgical patients, who were given rather small doses during a short period, may not be directly applied to intensive care patients. This consideration is supported by the main findings of this first study on effect-controlled administration of rocuronium in intensive care patients.

First, the dose required to maintain neuromuscular block decreased during the first 6–9 h and remained constant thereafter. Second, recovery time after administration of rocuronium for more than 24 h was prolonged moderately in comparison with administration up to 3 h in surgical patients. Third, in intensive care patients the volume of distribution at steady state was increased and terminal half-life

*Table 3* Main pharmacokinetic variables of rocuronium obtained from ICU patients (bolus and infusion) in the present study, and from two previous studies in surgical patients after rocuronium infusion of moderate duration (mean (SD) [range]; unless otherwise stated). $V^{ss}$ (ml kg$^{-1}$)=Volume of distribution at steady state; $T_{1/2}{}^{\beta}$ (min)=terminal half-life; *Cl* (ml kg$^{-1}$ min$^{-1}$)=clearance; MRT (min)=mean residence time (*Data from Sparr, Khuenl-Brady and Eriksson[2]; **data from McCoy and colleagues[3])

and mean residence time were prolonged compared with surgical patients with normal hepatic and renal function who received rocuronium for an intermediate duration.

A median dose of rocuronium of 27.4 mg $h^{-1}$ administered to patients in the bolus group was sufficient for smooth mechanical ventilation in ICU patients under adequate sedation and analgesia. In patients in the bolus group the next maintenance dose was not given before the second response in the TOF had reappeared. It occurred several times that three responses to TOF stimulation were detectable when the next bolus dose was given. Mean neuromuscular block in the bolus group was therefore approximately 80%.[12] Higher doses of rocuronium were administered to patients in the infusion group to maintain one response to TOF stimulation (i.e. 95% neuromuscular block). The median dose requirement in the infusion group (43.7 mg $h^{-1}$) in this study was comparable with that necessary in surgical patients for 90% neuromuscular block under i.v. anaesthesia.[2 17 18]

In patients in the bolus group, evaluation of dose requirements for rocuronium over time revealed a significant time effect (fig. 1). In addition, the doses of rocuronium administered to patients in both groups differed greatly from case to case. Therefore, monitoring of neuromuscular function is mandatory in ICU patients in order to adjust the dose to the individual needs of each patient and to avoid overdosing. Monitoring of neuromuscular function, however, does not eliminate prolonged weakness and myopathy in intensive care patients receiving neuromuscular blocking agents.[10 19] The results of this study suggest that a block of approximately 80%, which corresponds to that provided in the bolus group, may be sufficient to facilitate mechanical ventilation under adequate sedation and analgesia, even though some of the patients needed high levels of positive end-expiratory pressure and inversed-ratio ventilation for appropriate oxygenation. If, however, full relaxation of the diaphragm is desired, additional doses of rocuronium may be necessary to establish complete neuromuscular block of the diaphragm,[20] for example to prevent coughing on tracheal suction in patients with severe head injury.[21] The optimal level of neuromuscular block and the mode of administration of neuromuscular blocking agent (repeated bolus injections or continuous infusion) should be adapted to the individual needs of ICU patients.

None of the patients receiving rocuronium in this study showed prolonged recovery from neuromuscular block, if the definition given by Segredo and colleagues[7] is applied (i.e. failure to recover any response to ulnar nerve stimulation within 2 h after administration of the last dose of a neuromuscular blocking agent). However, recovery of neuromuscular function was moderately delayed in ICU patients compared with surgical patients who received an infusion of rocuronium for up to 3 h duration.[2 22] In this study recovery time was not related to the total dose of rocuronium given, duration of treatment, creatinine clearance or tests of liver function (aminotransferases, bilirubin). In 47% of patients in this study the time to attain a T4/T1 ratio of 0.7 was assessed using a small accelerometer (TOF Guard) designed for routine monitoring. The validity of TOF values obtained in the ICU setting using this device has not been investigated. In surgical patients, however, it was demonstrated that the limits of agreement are wide between TOF values obtained using this particular acceleration monitor and a mechanomyographic monitor, which is why these two monitoring systems should not be used interchangeably.[23]

In this study the pharmacokinetic variables of individual patients of both groups were analysed together, as the two different modes of rocuronium administration (single bolus dose *vs* continuous infusion) were not expected to produce different results. None of the putative metabolites of rocuronium was detected in any of the patients. In most subjects, the plasma concentration profile followed a two-exponential decay after the end of rocuronium administration, and no sign of non-linear kinetics were observed. However, in intensive care patients it is questionable if processes of drug distribution and elimination are linear and invariable in time. Therefore, the pharmacokinetics can be described only in global terms. It may be of more importance to take into account intra-individual variability as a result of (patho-) physiological changes such as diurnal rhythms, changes in organ perfusion and organ function, changes in the ratio between extra- and intravascular fluid content, and number of receptors. Up-regulation of receptors may lead theoretically to an increased level of rocuronium necessary to achieve the same degree of neuromuscular block. In this study there was no evidence of resistance to rocuronium, as the requirement for rocuronium was constant after more than 6–9 h of administration. Concomitantly administered drugs may interfere with the pharmacodynamics of rocuronium and possibly also with drug clearance.

The main pharmacokinetic variables of rocuronium in ICU patients were different compared with surgical patients,[2 3] that is volume of distribution at steady state was increased, plasma clearance was decreased and terminal half-life and mean residence time were prolonged. These pharmacokinetic variables may differ because of true differences between ICU and surgical patients. Clearance, for example, might be diminished as a result of impaired renal or hepatic function. Differences in pharmacokinetic variables may, however, be artefacts and result from differences in total duration of administration, total dose, plasma concentrations and sampling schedule. Plasma concentrations during the terminal phase were markedly higher after long-term administration, either by infusion or by repeated bolus doses, than after short-term administration. Therefore, plasma concentrations remained above the limit of quantification much longer than after short-term administration. As a result, the apparent half-life may be longer, even if the "true" half-life is similar. Consequently, the calculated volume of distribution at steady state also increased, and the calculated plasma clearance decreased.

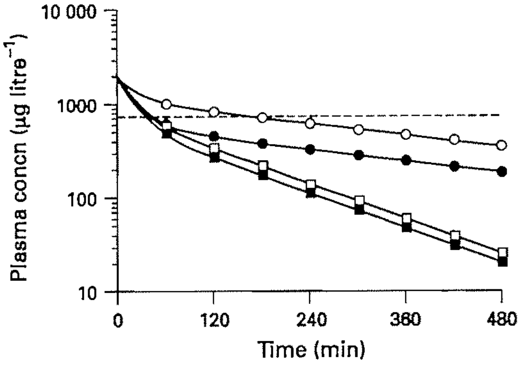

*Figure 3* Simulation of the plasma concentration profile of rocuronium after stopping a BET infusion producing a constant plasma concentration of 2000 μg litre$^{-1}$ over a period of 2 h (closed symbols) and 40 h (open symbols) in ICU patients (○, ●) and surgical patients (□, ■), respectively. The dashed line at 750 μg litre$^{-1}$ indicates the level at which 10% neuromuscular block was reached.

## Appendix

In order to investigate the consequences of the differences in drug disposition between ICU and surgical patients, the time course of the plasma concentration profile was simulated for both types of patients To clarify the influence of duration of drug administration, the plasma concentration was simulated after stopping an infusion lasting 2 and 40 h, respectively (fig. 3). These time values were chosen because they represent typical values of the duration of a rocuronium infusion in surgical patients[2 3]and in the ICU patients in this study, respectively.

For surgical patients the pharmacokinetic data of rocuronium were derived from a study in which rocuronium was administered as a bolus dose of 600 μg kg$^{-1}$ followed by a continuous infusion to maintain twitch height at 10% of control.[2] The mean pharmacokinetic variables of a two-exponential model were: clearance 4.51 ml kg$^{-1}$ min$^{-1}$, intercompartmental clearance 1.77 ml kg$^{-1}$ min$^{-1}$, $V^{c}$ 146 ml kg$^{-1}$ and $V^{ss}$ 310 ml kg$^{-1}$.

For ICU patients the mean pharmacokinetic data of this study were used.

For both types of patients the plasma concentration profile was maintained at a constant level of 2000 μg litre$^{-1}$ by means of bolus administration followed by an infusion with a continuously decreasing infusion rate according to the BET scheme.[24] After 2 and 40 h, respectively, the infusion rate was stopped, and the plasma concentration profile was followed for 8 h.

The plasma concentration profiles after stopping the infusion are depicted in figure 3. After 2 h of infusion, the plasma concentration decay in ICU patients was less rapid than that in surgical patients. However, the decay over the concentration range from 2000 to 750 μg litre$^{-1}$, which corresponds to approximately 90% and 10% neuromuscular block, was only slightly retarded in the ICU patients compared with the surgical patients.

In contrast, after 40 h of infusion, the decay after stopping the infusion was much slower in the ICU patients, and the time necessary to reach 750 μg litre$^{-1}$, or 90% recovery, was 160 min compared with 40 min in surgical patients. Simulations over a longer period of time resulted in approximately the same profiles as shown in figure 3, indicating that steady state had been reached.

As shown by the simulations, both duration of treatment and altered pharmacokinetics may be responsible for the alteration in the recovery profile in ICU patients compared with surgical patients.

# Predominant involvement of motor fibres in patients with critical illness polyneuropathy

E. HUND, H. GENZWÜRKER, H. BÖHRER, H. JAKOB, R. THIELE AND W. HACKE

## Summary

Critical illness polyneuropathy (CIP) is a recognized cause of muscle weakness and failure of weaning from a ventilator. In order to characterize the features of CIP, we have examined 28 consecutive surgical patients with severe sepsis using bedside electrophysiology. Of the 28 patients (median APACHE II score 31), 20 developed moderate to severe CIP, as shown by the presence of moderate to severe denervation activity on resting EMG. The median nerve compound muscle action potential (CMAP) amplitudes were reduced to 3.24 (SEM 0.48) mV, while sensory nerve action potential (SNAP) amplitudes obtained from the same nerve were normal (13.1 (1.9) μV). In approximately 50% of these patients, the reduction in CMAP exceeded 50% of the lower limit of normal. Similar results were obtained from stimulation of the ulnar nerve. We conclude that CIP is a major complication in patients with severe sepsis and prolonged artificial ventilation. It predominantly involves motor fibres and thus markedly interferes with weaning from the ventilator. (*Br. J. Anaesth.* 1997; **78**: 274–278).

**Key words**
Complications, critical illness polyneuropathy. Intensive care. Complications, sepsis.

In recent years, an acute and often severe axonal polyneuropathy has been recognized as a complication of sepsis and multiple organ failure.[1 2] Electrodiagnostically, this condition, termed critical illness polyneuropathy (CIP), has been found in up to 70% of patients suffering from sepsis or multiple organ failure.[3] The clinical features include flaccid quadriplegia, hyporeflexia and muscular atrophy. Difficulty in weaning affected patients from the ventilator prolongs stay in the intensive care unit (ICU) and increases morbidity and mortality. Involvement of both sensory and motor nerve fibres has been suggested,[4 5] although clinically the motor syndrome predominates. The purpose of this study was to further characterize the features of CIP using electrophysiology.

## Patients and methods

After obtaining institutional Ethics Committee approval and informed consent from each patient's next of kin, we studied 28 surgical patients from our ICU who had evidence of sepsis and required prolonged mechanical ventilation. Seven additional patients with a previous history of neuromuscular disease, diabetes mellitus, uraemia or alcoholic liver disease were excluded. Sepsis was defined according to the criteria of the ACCP/SCCM.[6] All patients underwent neurological examination and electrodiagnostic studies at the bedside using a Dantec Cantata instrument (Dantec Inc., Copenhagen, Denmark). Data were obtained on days 5–7 after the onset of mechanical ventilation, and repeated weekly within the first month and on a 2-week schedule over the next 2 months. Thereafter, a 3-week schedule was used if the patient was still in the ICU.

For sensory measurements, antidromic recordings were made from the median nerve using ring electrodes and from the sural nerve using needle electrodes. For each measurement, 20 responses were averaged. Compound muscle action potentials (CMAP) were recorded with surface electrodes from the abductor pollicis brevis muscle after supramaximal stimulation of the median nerve at the wrist and elbow. Similarly, the ulnar, peroneal and tibial nerves were stimulated, and responses were recorded from the abductor digiti minimi and the abductor hallucis muscles, respectively (table 1). Amplitudes of the compound action potentials were measured as the maximum peak-to-peak voltage after distal stimulation. Nerve conduction velocity was determined according to standard procedures.[7] At least one proximal and one distal arm muscle were examined by needle electromyography (EMG). Abnormal spontaneous activity, as shown by the presence of fibrillation potentials and positive sharp waves in resting muscles, was graded on a scale of 0–3, where 0 is normal, 1 mild, 2 moderate and 3 severe.[5 8] Patients with grade 2 and 3 denervations were considered to have definite CIP severe enough to cause or contribute to weaning failure, and those

with grade 1 denervations were deemed to have mild neuropathy that would not account substantially for weaning failure. Neuromuscular transmission was assessed by repetitive stimulations at 3 and 30 Hz. Vitamins, including thiamine, pyridoxine and cobalamin, were administered generously, starting early in the disease course. Serum concentrations of electrolytes, including phosphate and magnesium, were measured repeatedly and maintained within the normal range by frequent i.v. supplementation. Neuromuscular blocking agents were given only infrequently and on an intermittent basis. Results are given as mean (SEM).

## Results

We studied 28 patients, aged 16–80 yr (table 2). Median APACHE II score was 31 (range 23–38, 10 survivors). Eighteen of these patients died 7–143 days after admission to the ICU. The 10 survivors were weaned from the ventilator within 9–84 days after initiation of mechanical ventilation.

Of the 28 patients, 20 developed grade 2–3 denervation potentials on resting EMG (fig. 1). Median time to develop grade 2 to 3 denervations was 21 days after admission to the ICU, with the earliest occurrence of grade 1 denervations on day 8 and grade 2 denervations on day 11. In a patient admitted because of sepsis, grade 3 denervations were already present at the initial examination on day 4. Of the eight patients who had no or only few denervation potentials, seven died within the first 2 weeks and the remaining patient died on day 24. On neurography, there were normal or near-normal conduction velocities and distal latencies in all patients (table 3).

In the 20 patients with grade 2 and 3 denervations, CMAP amplitudes of the median nerve were

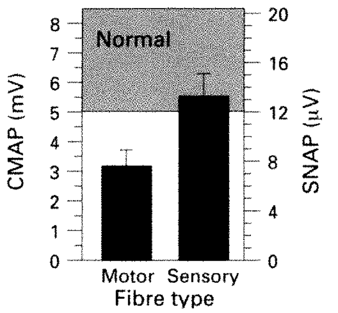

*Figure 2* Compound muscle (CMAP) and sensory nerve (SNAP) action potential amplitudes after supramaximal stimulation of the median nerve in 20 patients with sepsis and prolonged mechanical ventilation.

reduced to 3.24 (SEM 0.48) mV, while sensory nerve action potential (SNAP) amplitudes from this nerve were normal (fig. 2). In 12 of these patients, median nerve CMAP amplitudes were less than 50% of the lower limit of normal, ranging from only 57 µV to 1.84 mV, while median nerve SNAP amplitudes were not significantly reduced. An additional five patients with no or only grade 1 denervations also had decreased median nerve CMAP and normal SNAP. These five patients died early during the disease. Similar results were obtained from the ulnar and peroneal nerves, while CMAP from stimulation of the tibial nerve were not significantly reduced. Sural nerve action potentials were normal. Repetitive stimulation studies with short and long runs were found to be normal in all patients. None of the patients had features of demyelination that would indicate a far worse diagnosis.[9]

Serum creatine kinase (CK) concentrations from 23 patients were normal in 15 and slightly increased in eight. The highest CK concentrations were found in a patient with multiple trauma (477 iu litre$^{-1}$; normal <80 iu litre$^{-1}$). Two patients underwent muscle biopsy which revealed neurogenic changes and slight myopathy, preferentially affecting type II fibres. Lumbar puncture was performed in four patients and revealed no abnormalities. Clinically, most patients developed generalized and marked muscular atrophy during their stay in the ICU. On palpation, the musculature gave a peculiar soft and pasty impression. As far as patients could be examined, they were found to have severe flaccid tetraparesis. Sensory testing was impossible because of sedation or encephalopathy in the majority of patients. In most patients, tendon reflexes were decreased but present, even in those with severe CIP.

## Discussion

Of the 28 patients in this study, 20 (71%) developed moderate to severe CIP according to the EMG results. On neurography, these 20 patients had abnormal CMAP and normal SNAP from stimulation of the median and ulnar nerves. Similarly, peroneal CMAP were reduced while sural SNAP were normal. This discrepancy between motor and sensory amplitudes was consistent in repeated examinations. In approximately 50% of these patients, the discrepancy was particularly evident. This finding indicates a predominant involvement of motor nerves by CIP and suggests that weaning from the ventilator may not be possible in individual patients with severe CIP. Thus forced weaning manoeuvres may endanger these patients unnecessarily. Bedside electrophysiological studies should aid in early recognition of CIP and monitoring of its course. Such a strategy may allow a rational approach to be adopted when weaning septic patients from the ventilator. The reason why tibial CMAP were not reduced significantly is not known; it is not clear if this indicates a predilection of CIP for specific nerves.

There is some evidence from the literature that CIP affects motor fibres to a greater extent than sensory fibres. In Bolton and colleagues' original series, patients with CIP demonstrated decreased motor amplitudes to 30% of control levels at the nadir of the illness, while sensory amplitudes reached 60% of control levels.[10] In contrast, in patients with Guillain–Barré syndrome, the amplitudes of both fibre types were depressed to equally low levels (25% of control). Coakley and colleagues described a motor axonal syndrome in three patients undergoing mechanical ventilation for obstructive pulmonary disease, two with complete absence of any sensory involvement.[11] In another series, 12 of 27 patients showed normal SNAP but abnormal CMAP amplitudes,[12] and similar findings have been observed by others.[2 13–15] Moreover, several sural nerve biopsies obtained at the time of severe muscle wasting showed no signs of axonal degeneration.[2 14]

The selective decrease in CMAP amplitudes raises the question of disturbed neuromuscular transmission, myopathy, lesions to the anterior horn cells and the motor variant of Guillain–Barré syndrome.[16] Prolonged neuromuscular block has been observed in patients treated with high doses of non-depolarizing neuromuscular blocking agents (for review, see Watling and Dasta[17]). However, in most CIP series, including our study, such agents were administered only infrequently and in low doses.[2 3 11] Moreover, repetitive nerve stimulations in our patients and in others[4 18] provided no evidence of disturbance at the neuromuscular junction.

Different types of myopathy have been described with increasing frequency in ICU patients. In a subgroup, necrosis of myofibres occurs, provisionally termed "necrotizing myopathy of intensive care".[19–21] Such patients are frequently admitted for acute severe asthma, have markedly increased CK concentrations, are generally non-septic and have received high-dose steroids, non-depolarizing neuromuscular blocking agents, or both.[22] Other ICU patients with acute myopathy do not develop significant increases in serum CK concentrations, and muscle biopsy does not reveal widespread necrosis.[21 23] Such patients may have various types of histopathological abnormalities, including unselective atrophy of both type I and type II fibres, increased intracellular lipid droplets, scattered necrosis and moth-eaten fibres.[18] More specific abnormalities include selective loss of thick (myosin) myofilaments,[23 24] inexcitability of muscle membranes[25] and acute type II muscle fibre atrophy.[26]

Only a minority of our patients had increased serum CK concentrations. These increases were slight to moderate despite the fact that many patients had recent trauma, major surgery or soft tissue inflammation. None was admitted because of asthma. Eight of 12 patients with severely reduced CMAP amplitudes had normal CK concentrations, rendering necrotizing myopathy a less likely mechanism. Muscle biopsy performed in two patients in whom myopathy was suspected revealed neurogenic changes accompanied by only slight myopathy. Such unspecific myopathy is frequently present in patients with CIP.[5]

Severe cases of CIP should be distinguished from the acute motor axonal variant of Guillain–Barré syndrome, which is an immune-mediated disease most commonly associated with *Campylobacter jejuni* infections.[27] In contrast, CIP is a non-immune disorder restricted to ICU patients and related closely to severe infection or trauma of virtually any type, including sepsis and the systemic inflammatory response syndrome.[1,28] Unlike in Guillain–Barré syndrome, there is no evidence of inflammation in nerve biopsies.[1] Thus the pathogenesis of the two syndromes and the setting in which they occur is invariably different. To the best of our knowledge, no critically ill patient developing flaccid tetraplegia has yet been diagnosed with the axonal variant of Guillain–Barré syndrome. However, recognizing occasional patients in the ICU with Guillain–Barré syndrome is important because they may respond to plasma exchange and i.v. immunoglobulins.[28] Unfortunately, electrodiagnostic criteria allowing differentiation of motor axonal Guillain–Barré syndrome from CIP have not yet been established, making further investigations (e.g. lumbar puncture and nerve biopsy) necessary.

Other diagnostic considerations include damage to anterior horn cells resulting from acute or chronic spinal cord ischaemia[2,29,30] and acute motor neuropathy associated with administration of non-depolarizing neuromuscular blocking agents.[1] No episodes of severe hypoxia or hypotension occurred in our patients and anterior horn cell changes suggestive of ischaemia probably occurred only preterminally in two autopsy cases.[5] Neuromuscular blocking agents were administered in our patients only infrequently and on an intermittent basis. In none did repetitive nerve stimulations suggest disturbance of neuromuscular transmission. In addition, only the non-steroidal agent atracurium was used.

Until now, the pathophysiological events that cause CIP have remained unclear. Although a variety of potential causes such as types of primary illness or injury, medications (e.g. aminoglycosides and neuromuscular blocking agents) and specific nutritional deficiencies have been considered, retrospective and prospective studies failed to implicate them as causative factors.[1] Bolton has speculated that the mechanisms responsible for the systemic effects of sepsis may also cause axonal degeneration.[1] As a mechanism, he suggested disturbances in the microcirculation of peripheral nerves. However, biopsies from affected patients did not reveal fascicular infarction, microangiopathy, oedema or intravascular thrombus formation.[5,31] Moreover, this concept would not explain the predominance of CIP for motor nerve involvement.

In summary, CIP occurs frequently in septic patients and involves predominantly motor nerve fibres. Affected patients show an unusual combination of normal SNAP amplitudes, markedly decreased CMAP amplitudes and prominent denervation. Bedside electrophysiology may help to diagnose and monitor CIP, thus avoiding futile attempts to wean patients from the ventilator. Recognizing the predilection for motor nerves may be helpful in clarifying the pathogenesis of the disease.

# Propofol attenuates formation of lipid peroxides in tourniquet-induced ischaemia–reperfusion injury

S. KAHRAMAN, K. KILINÇ, D. DAL AND K. ERDEM

## Summary

We studied 20 adult ASA I patients undergoing elective peripheral surgery allocated randomly to one of two groups. In the propofol group (*n*=9) anaesthesia was induced with propofol and fentanyl followed by continuous infusion of propofol. In the control group (*n*=11), after induction of anaesthesia with thiopentone and fentanyl, anaesthesia was maintained with isoflurane. Concentrations of lipid peroxides in both plasma and muscle tissue samples were measured as thiobarbituric acid-reacting substances (TBARS). Plasma TBARS concentrations increased significantly in the control group at 1, 5, 15, 30 and 45 min after release of the tourniquet to mean 1.83 (SD 0.13), 2.00 (0.12), 2.25 (0.14), 2.30 (0.12) and 2.41 (0.14) μmol litre$^{-1}$, respectively, compared with pre-reperfusion values (1.64 (0.14) μmol litre$^{-1}$). In the propofol group this was significant only at 30 min (1.85 (0.03) *vs* 1.74 (0.04) μmol litre$^{-1}$). TBARS concentrations of reperfused muscle tissue were significantly higher than pre-reperfusion concentrations in the control group (70.30 (10.06) *vs* 52.13 (5.73) nmol/g wet tissue). We conclude that propofol attenuated ischaemia–reperfusion-induced lipid peroxidation in the therapeutic doses used in anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 279–281).

**Key words**
Anaesthetics i.v., propofol. Muscle skeletal, lipid peroxides. Complications, ischaemia–reperfusion injury.

Re-introduction of oxygen to an ischaemic or hypoxic tissue has been shown to cause additional insult to the tissue (reperfusion injury). Reactive oxygen species which damage cellular components and initiate the lipid peroxidation process are known to be responsible for the ischaemia–reperfusion injury. Lipid peroxidation is a chain reaction leading to oxidation of polyunsaturated fatty acids which, in turn, disrupts the structure of biological membranes and produces toxic metabolites such as malondialdehyde (MDA). The thiobarbituric acid assay, which measures MDA, has served as the most commonly used method for measuring lipid peroxidation.

Propofol (2,6-diisopropylphenol) is chemically similar to phenol-based free radical scavengers such as butylated hydroxytoluene and the endogenous antioxidant α-tocopherol (vitamin E).[1–3] Propofol has been shown to exhibit significant antioxidant activity *in vitro*, reacting with free radicals to form a phenoxyl radical.[3 4] Although Green, Bennett and Nelson[1] suggested that the antioxidant activity of propofol may not be clinically relevant, this effect has also been demonstrated at anaesthetic concentrations.[2] However, no clinical study has been conducted in humans to investigate the antioxidant effect of anaesthetic doses of propofol in ischaemia–reperfusion injury of skeletal muscle.

Therefore, we have determined if infusion of propofol would prevent the formation of lipid peroxides as a result of tourniquet-induced ischaemia–reperfusion injury in surgery of the limbs.

## Patients and methods

After obtaining Ethics Committee approval and informed patient consent, we studied 20 adult, ASA I patients undergoing peripheral surgery using a tourniquet. Patients were allocated randomly by closed envelope method to one of two groups: propofol (*n*=9) and isoflurane (control, *n*=11). No patient was receiving vitamin supplements. All patients were premedicated with diazepam 10 mg orally, 45 minutes before surgery. In the propofol group anaesthesia was induced with propofol 2–2.5 mg kg$^{-1}$ and fentanyl 3 μg kg$^{-1}$ followed by continuous infusion of propofol at a rate of 10 mg kg$^{-1}$ h$^{-1}$, reducing to 8 and 6 mg kg$^{-1}$ h$^{-1}$, respectively, at 10-min intervals. The maintenance dose was adjusted to clinical signs and anticipated demand. In the control group anaesthesia was induced with thiopentone 5 mg kg$^{-1}$ and fentanyl 3 μg kg$^{-1}$, and maintained with 1% isoflurane. Vecuronium 0.1 mg kg$^{-1}$ was given to facilitate tracheal intubation in both groups and the lungs were ventilated with 60% nitrogen in oxygen. The tourniquet was applied at a pressure approximately twice the systolic arterial pressure.

Using heparin-locked i.v. catheters, sequential

venous blood samples were obtained from the antecubital vein of the contralateral arm. The dorsal vein of the foot was used for i.v. fluid and propofol infusions. During lower limb operations one arm was used for blood sampling and the other for i.v. fluid infusions.

Blood samples for lipid peroxidation analysis were obtained immediately before and 1, 5, 15, 30, 45 min after tourniquet release. Blood samples for measurement of blood urea nitrogen, creatinine, creatinine phosphokinase, lactate, sodium, potassium and calcium concentrations and muscle tissue biopsy samples were obtained immediately before (control) and 20 min after release of the tourniquet (reperfusion).

Plasma samples were centrifuged immediately. The supernatant and muscle tissue samples were stored at −70 °C until analysis. Concentrations of lipid peroxides in both muscle tissue and plasma samples were measured as thiobarbituric acid-reacting substances (TBARS). Frozen tissues were immediately weighed and homogenized in 10 volumes of ice-cold phosphate buffer (50 mmol litre$^{-1}$, pH 7.4) using a glass–glass homogenizer (B. Brown, Germany). The homogenate (0.5 ml) was mixed with 3 ml of 1% $H_3PO_4$. After addition of 1 ml of TBA reagent (0.67%) the tubes were heated in boiling water for 45 min. The colour formed was extracted into 4 ml of n-butanol. After centrifugation, the colour intensity of the butanol layer was measured at 532 nm using a Shimadzu UV-120-02 model spectrophotometer.[5] Tetramethoxypropane was used as the standard and concentrations of TBARS were calculated as nanomoles of malondialdehyde (MDA) per gram of wet tissue. Lipid peroxide concentrations in plasma were measured as described by Wade and van Rij.[6] Concentrations of TBARS in serum were calculated as micromoles per litre.

Significant differences between groups were analysed using the Mann–Whitney *U* test. Intragroup comparisons were performed by Wilcoxon matched pairs test and $P<0.05$ was considered statistically significant.

## Results

There were no significant differences between groups in age, weight, sex distribution or tourniquet time (table 1). Plasma concentrations of TBARS increased significantly in the control group at 1, 5, 15, 30 and 45 min after release of the tourniquet by mean 1.83 (SD 0.13), 2.00 (0.12), 2.25 (0.14), 2.30 (0.12) and 2.41 (0.14) μmol litre$^{-1}$, respectively, compared with pre-reperfusion values (1.64 (0.14) μmol litre$^{-1}$) (fig. 1). In contrast, there were only slight increases at 15, 30 and 45 min in the propofol group, and this was significant only at 30 min (1.80 (0.03), 1.85 (0.03) and 1.83 (0.06) μmol litre$^{-1}$, respectively, *vs* 1.74 (0.04) μmol litre$^{-1}$).

*Table 1* Patient characteristics (mean (SD or range) or number)

| | Group I (isoflurane) | Group II (propofol) |
|---|---|---|
| *n* | 11 | 9 |
| Age (yr) | 36.55 (29–59) | 36.77 (18–58) |
| Weight (kg) | 73.34 (15.5) | 80.55 (13.7) |
| Sex (M/F) | 7/4 | 6/3 |
| Operation (*n*) | | |
| Median nerve exploration | 3 | 3 |
| Ulnar nerve exploration | 1 | — |

| Intramuscular hamartoma | 1 | 1 |
| Achilloplasty | 2 | 1 |
| Contracture release | 2 | 3 |
| Tourniquet time (min) | 82.55 (26.1) | 89.20 (23.7) |
| Anaesthesia time after tourniquet release (min) | 46.36 (14.5) | 47.78 (12.5) |

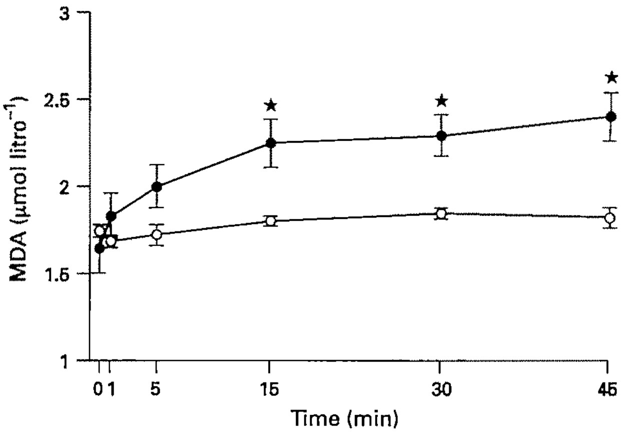

*Figure 1* Plasma MDA concentrations before (0) and 1, 5, 15, 30 and 45 min after release of the tourniquet in the isoflurane (●) and propofol (○) groups. *$P<0.05$ between groups.

TBARS concentrations in muscle tissue after 20 min of reperfusion were significantly higher than pre-reperfusion concentrations in the control group (70.30 (10.06) *vs* 52.13 (5.73) nmol/g wet tissue) while there were no significant differences in the propofol group (38.13 (5.26) *vs* 40.16 (5.68) nmol/g wet tissue). TBARS concentrations in reperfused muscle tissue were significantly different between groups ($P=0.0069$).

In two patients (22%) in the propofol group and four patients in the control group the anaesthetic was discontinued before 45 min of reperfusion. Plasma electrolyte, creatinine, blood urea nitrogen, lactate and creatinine phosphokinase concentrations were not significantly different after reperfusion in either group and differences between groups were not significant.

## Discussion

Although skeletal muscle is fairly resistant to ischaemic injury, ischaemia–reperfusion injury has been documented in previous studies. Concannon and colleagues[7] showed a significant increase in MDA production within 2 h in a rabbit model of tourniquet-induced skeletal muscle ischaemia–reperfusion injury. The results of our study (35% increase in MDA concentrations in muscle tissue after 20 min of reperfusion and 47% increase in systemic blood within 45 min after reperfusion) were comparable with the results of Concannon and colleagues.

Studies using isolated organelles have shown that propofol inhibits lipid peroxidation induced by oxidative stress in rat liver mitochondria, microsomes and brain synaptosomes.[2,4] However, its effects on skeletal muscle ischaemia–reperfusion injury have not been examined. Intentional ischaemia (tourniquet)–reperfusion for bloodless upper limb surgery has been accepted as a good human model for ischaemia–reperfusion injury. In this human model of ischaemia–reperfusion injury, we examined the effect of the i.v. anaesthetic propofol on lipid peroxide formation. As it was shown that maintenance of general anaesthesia with clinical relevant concentrations of nitrous oxide or isoflurane were not associated with an increase in toxic oxygen metabolites[8] we preferred to use isoflurane in the control group. While there was a significant increase in MDA concentrations in both plasma and muscle tissue in the isoflurane group, there was only a slight increase in plasma concentrations in the propofol group. The absence of a significant difference in biochemical variables at 20 min of reperfusion suggests that our measurements were probably performed after the initial rapid washout of accumulated tissue lactate and other substances.

We conclude that propofol attenuated ischaemia–reperfusion-induced lipid peroxidation when given in the therapeutic doses used in anaesthesia; this suggests that its oxygen free radical scavenging activity during anaesthesia is likely to be clinically significant.

# Auditory evoked response, median frequency and 95% spectral edge during anaesthesia with desflurane and nitrous oxide

R. M. SHARPE, D. NATHWANI, S. K. PAL, M. D. BRUNNER, C. THORNTON, C. J. DORÉ AND D. E. F. NEWTON

## Summary

We have studied in 12 patients the effect of desflurane in nitrous oxide on the electroencephalogram (EEG) and the early cortical auditory evoked response (AER). After induction with desflurane, patients' lungs were ventilated to maintain three different end-expiratory concentrations of desflurane (1.5, 3 and 6%) during four consecutive 10-min periods before surgery. As the end-expiratory concentration of desflurane was increased, Pa and Nb (AER) amplitudes decreased and their latencies increased, and spontaneous EEG showed an increase in amplitude and a slowing of frequency. A linear relationship was demonstrated between $\log_{10}$ concentration of desflurane and all variables ($P=0.001$). Pa amplitude showed the greatest linearity followed by the derived variable F95 of the EEG. From regression slopes, mean percentage changes of each variable were calculated for a 1 MAC change in desflurane concentration. Pa amplitude showed the largest change (mean 49% (95% confidence interval 40–56%) decrease for a 1 MAC increase). This was greater than that of F95 for a similar confidence interval, indicating better resolution. This study confirms that the early cortical AER is affected by desflurane in a similar manner to that of other anaesthetic agents and as such remains the most promising EEG derived measure of depth of anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 282–285).

Anaesthesia, depth. Anaesthetics volatile, desflurane. Monitoring, electroencephalography. Brain, evoked potentials.

Previous studies have shown that increasing concentrations of inhalation[1 2] and i.v.[3 4] anaesthetic agents produce graded reductions in amplitude and prolongation of the latency of waves Pa and Nb of the early cortical auditory evoked response (AER). These changes are not agent specific and are antagonized by surgical stimulation,[5] suggesting that the AER may be a useful measure of anaesthetic depth.

The electroencephalograph (EEG) has been shown to slow with increasing concentration of anaesthetic, although enflurane has an opposite effect.[6] EEG data may be analysed to provide quantitative indices. Variables can be derived from the power spectra of the EEG, for example median frequency or F50, which is the frequency below which 50% of the signal power is present, [7] and spectral edge frequency or F95 which is the frequency below which 95% of the signal power is present.[8] Spectral edge and median frequencies have been shown to decrease with increasing concentrations of thiopentone,[9] etomidate,[10] isoflurane[11] and desflurane.[12]

The EEG and AER effects of new agents have to be characterized if they are to remain useful tools for monitoring depth of anaesthesia. The aims of this study were to investigate the effects of desflurane on the early cortical AER and to compare these with changes in median frequency and spectral edge of the EEG.

## Patients and methods

We studied 12 patients, aged 31–65 yr, undergoing elective surgery requiring tracheal intubation. All gave informed consent to participate in the study, the design of which was approved by the Harrow District Ethics Committee.

After premedication with morphine 10 mg and atropine 0.4 mg i.m., anaesthesia was induced by inhalation of desflurane and 66% nitrous oxide (end-tidal) in oxygen. When anaesthesia was achieved, vecuronium 0.1 mg $kg^{-1}$ was given and the patient's trachea intubated. The lungs were ventilated with desflurane and 66% nitrous oxide in oxygen, a concentration selected according to a predefined sequence to which patients had been allocated randomly. Patients received either 1.5, 3 or 6% desflurane (end-expiratory concentrations) for 10 min and then the concentration was changed. All patients received each of the three possible concentrations. During a fourth period, the concentration of the preceding period was repeated. This study

design ensured that each concentration of desflurane followed every other concentration, including itself, an equal number of times so that overall, any "carry over" effect of one period to the next would be cancelled. It also allowed interactions between dose and time to be studied. Fresh gas flow was adjusted to maintain end-expiratory carbon dioxide partial pressure at 4.5–5 kPa. Neuromuscular block was maintained at a level of two responses on the train-of-four by infusion of vecuronium. End-expiratory concentrations of nitrous oxide, carbon dioxide and desflurane were measured using a calibrated Datex Ultima gas analyser.

The EEG and AER recorded from adhesive silver–silver chloride electrodes attached to the mastoid and forehead were stored and analysed on a PC-based system described previously.[13] The auditory stimulus was a rarefaction click at 6 per second delivered to both ears via close fitting ear pieces, 75 dB above the average hearing threshold. The EEG signal was analogue filtered on input with bandwidths of 25–500 Hz to produce the AER recording. Although the EEG and AER were recorded continuously throughout the study, only the last 2 min 40 s (1024 sweeps of AER) of each period, when equilibration was considered to have occurred, were used to derive the data. From the printed AER waveforms, Pa and Nb amplitudes and latencies were measured by an observer blind to the dose of desflurane.

For statistical analysis, all AER variables were normalized by $\log_{10}$ transformation. To test for a significant effect of dose and period on the AER and EEG variables, we used analysis of variance (ANOVA) with the restricted maximum likelihood (REML) procedure in Gentstat.[14] The Wald statistic (REML) which follows an approximate chi-square distribution with 1 degree of freedom tested for linearity with log dose.

## Results

Of the 12 patients studied, eight were females undergoing major gynaecological surgery and four were males undergoing major orthopaedic surgery. Mean age was 46 (range 31–62) yr and mean weight 77 (SD 10) kg.

As the end-expiratory concentration of desflurane was increased, Pa and Nb amplitudes decreased and their latencies increased, and the EEG showed an increase in amplitude and a slowing of frequency. An example from one patient is shown in figure 1.

A linear relationship was demonstrated between $\log_{10}$ dose and all variables over the concentration range studied. For example, mean Pa amplitude and F95, plotted against end-expiratory desflurane concentration ($\log_{10}$ scale) are shown in fig. 2.

For all variables the Wald statistic was highly significant at $P<0.001$ (table 1). The Wald statistic

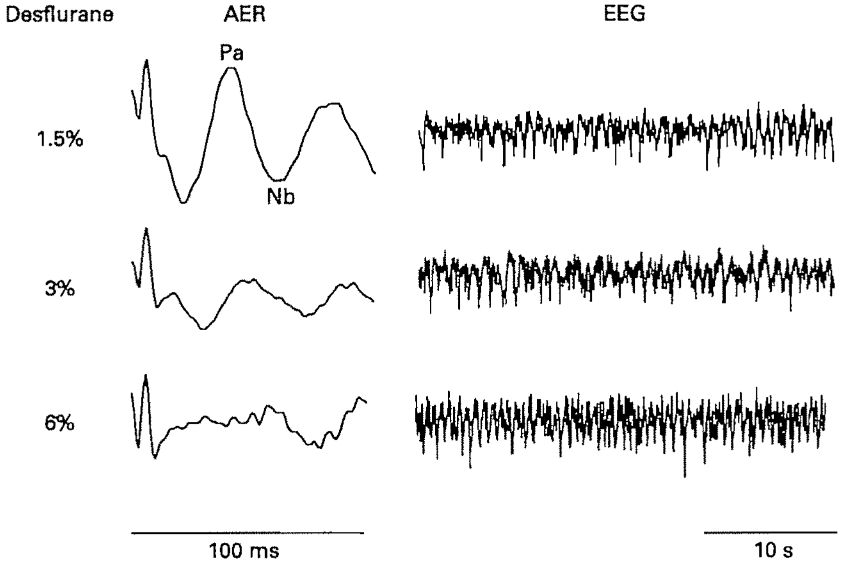

*Figure 1* An example from one subject, showing the effect of increasing end-expiratory desflurane on the AER and EEG. In the AER the amplitudes of Pa and Nb decreased and their latencies increased. The EEG shows an increase in amplitude and slowing of frequency.

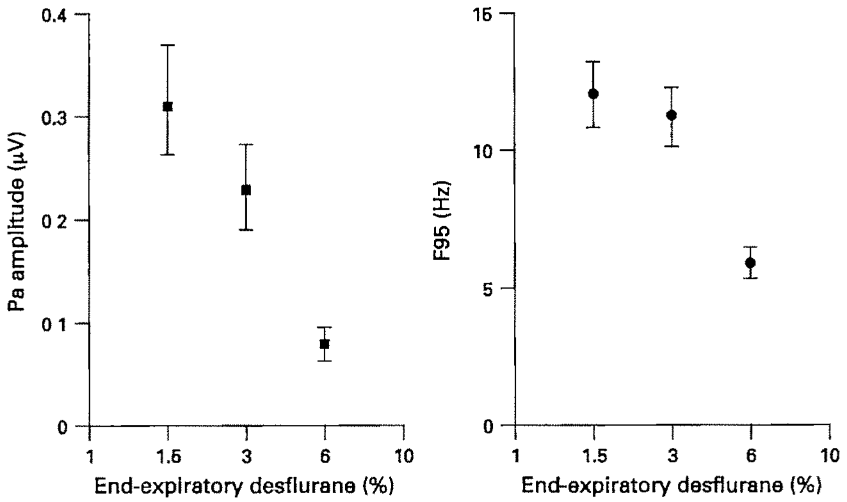

*Figure 2* Mean (95% confidence intervals) Pa amplitude and F95, plotted against desflurane concentration (log scale).

tests for linearity and the larger the number the more linear the relationship. Pa amplitude had the highest value, followed by F95. Regression slopes (with SEM) for each variable with $\log_{10}$ dose were calculated. From these, the percentage change and 95% confidence intervals were calculated for a 1 MAC increase in desflurane concentration. For example, a 1 MAC increase in desflurane concentration produced a 49% (95% confidence interval 40–56%) decrease in Pa amplitude, and a 33% (25–41%) decrease in spectral edge. Percentages are appropriate rather than the original units because the AER and EEG variables were $\log_{10}$ transformed for data analysis.

A period effect was seen for Pa and Nb amplitudes, and F50 and F95 ($P$=0.009, 0.01, 0.003 and <0.001, respectively). The means of these variables were significantly lower in the later periods of administration (table 2). In the case of Pa amplitude and F95, a significant interaction between dose and period was seen ($P$=0.05 and <0.001, respectively). For the low desflurane concentration these variables decreased in the later periods. At medium and high concentrations no clear trend emerged.

## Discussion

Desflurane reduced the amplitudes of waves Pa and Nb of the AER and increased their latencies. Median frequency (F50) and spectral edge (F95) were reduced by desflurane. In all cases these effects were linearly dose related.

The significant effect of period on the variables Pa and Nb amplitude and F50 and F95 suggests that although end-expiratory desflurane concentration equilibrated rapidly with inspired desflurane concentration in each of the four periods, equilibration in the brain had not occurred in the earlier periods. In the later periods the means of the above variables were lower (the patients were deeper) despite being exposed to the same concentrations of desflurane (table 2).

In addition, an interaction between dose and period was seen for Pa amplitude and F95. For the lowest desflurane concentration, these variables were lower (the patients were deeper) in the later periods. No trend was seen for the medium and high concentrations. As the low desflurane concentration could only follow a higher concentration (except in the first period) this effect could be attributed to a carry over effect from the preceding period. If this were true one would expect to see the converse effect in the high desflurane concentration group. However, such an effect was not observed. There are two possible explanations for this: first, the same equilibration effects cannot be assumed during wash-in and wash-out; second, for the AER variables, the effect may have been too subtle to detect at the higher desflurane concentrations where the average curves were much flatter.

Changes in the early cortical AER were similar to those of other anaesthetics we have studied previously.[1–4] Halothane, enflurane, isoflurane, etomidate and propofol reduced amplitude and increased the latency of the Pa and Nb waves of the AER in a dose-related manner. Confirmation that new anaesthetic agents produce similar changes in the AER strengthens its value as a method of monitoring depth of anaesthesia.

Changes in the AER were more marked when the concentration of desflurane decreased from 3% to 1.5% compared with changes in EEG variables (see fig. 1). Thus the AER may be a more sensitive indicator of anaesthetic depth at low desflurane doses than the EEG.

Pa amplitude showed the best linear relationship with desflurane concentration (largest Wald statistic, F95 was the next largest (table 1)). Also, Pa amplitude showed a larger percentage change for 1 MAC desflurane compared with F95 for the same confidence intervals, suggesting greater resolution of measurement.

Rampil and colleagues investigated the quantitative effects of desflurane on the EEG[12] and found a progressive decrease in these variables with increasing concentration. However, at comparable desflurane concentrations, F50 and F95 were higher in their study compared with ours. Patients in our study were deeper for equivalent desflurane concentrations, possibly because of premedication with morphine and atropine as an adjunct to induction with desflurane. We used this premedication and nitrous oxide for comparison with data from our previous studies with other volatile agents.[1 2] In addition, the higher mean age of the patients in the this study of 45.8 yr compared with 23.8 in the study of Rampil and colleagues would contribute to this difference. Burst suppression was not seen in our study.

In summary, we observed that desflurane had similar actions on the early cortical AER as other anaesthetic agents studied previously and it compared well with EEG spectral analysis variables. Pa amplitude (AER) showed better linearity and resolution than the best of the EEG variables (F95). The results also suggested that the AER may be a more sensitive indicator of anaesthetic depth at low desflurane doses and the EEG more sensitive at higher desflurane concentrations. As such, the early cortical AER remains the most promising EEG derived measure of depth of anaesthesia.

# Effect of percutaneous local anaesthetics on pain reduction during pulse dye laser treatment of portwine stains

D. F. McCAFFERTY, A. D. WOOLFSON, J. HANDLEY AND G. ALLEN

## Summary

We have used EMLA, 4% amethocaine gel and placebo for facial portwine stains, for a period of 1 h, in a double-blind study. After removal of the preparations from the skin surface, each area was treated with six pulses of the laser, each 5 mm in diameter. Any pain noted immediately after treatment was recorded using both visual analogue (VAS) and verbal rating (VRS) scores. Twenty nine patients completed the study and statistical analysis of the results indicated that both EMLA and 4% amethocaine gel were superior to placebo ($P<0.001$). However, when EMLA and 4% amethocaine gel were compared, the amethocaine preparation was significantly better ($P<0.05$, VAS; $P<0.005$ VRS) than EMLA in reducing pain caused by the laser treatment. (*Br. J. Anaesth.* 1997; **78**: 286–289).

**Key words**
Anaesthetics local, amethocaine. Anaesthetics local, EMLA. Complications, portwine stains.

Portwine stains (PWS) are benign, disfiguring vascular birthmarks consisting of ectatic dermal capillaries. They are relatively common with an incidence of approximately 0.3% in the general population. The former are caused by malformed blood vessels close to the skin surface. As approximately 80% of portwine stains are found on the face or neck this disfiguration can lead to various psychosocial problems. Current treatment of these lesions involves the use of a pulse dye laser which emits a pulsed coherent light of wavelength 585 nm which is absorbed selectively by oxyhaemoglobin in capillaries. The pulse duration of 450 μs is less than the thermal relaxation time of the dermal capillaries which enables the incident laser light to photocoagulate the capillaries while minimizing thermal diffusion into surrounding tissue. As a result, the possibility of scarring is reduced. The pulse dye laser has proved to be both effective and safe and is currently considered the treatment of choice for portwine stain birthmarks.

However, this treatment can be painful, especially if large areas are involved. Young children often require general anaesthesia before this procedure and older patients some type of local anaesthesia. It has been reported that EMLA cream, when applied for a period of 1–2 h before treatment, can reduce the pain associated with this procedure.[1] In our experience, however, when applied for 2 h or more before treatment, EMLA provided only partial pain relief.

An amethocaine-based preparation has been shown to provide more effective percutaneous local anaesthesia than EMLA.[2] Therefore, the purpose of this double-blind study was to compare the efficacy of the two formulations with placebo for prevention of pain during treatment of portwine stains by pulse dye laser.

## Patients and methods

### FORMULATIONS

EMLA was obtained from Astra, UK, and amethocaine gel 4% w/w was prepared as described previously.[2] A placebo gel was also prepared to match the two active formulations. All three formulation were packaged into standard lacquered aluminium tubes, using standard pharmaceutical methods. Each tube was then assigned a randomized number.

### PATIENT SELECTION

Ethics Committee approval was obtained for the study and of the 30 patients enrolled, 29 completed the treatment. Inclusion criteria were age more than 12 yr of age, a portwine stain of at least 3×3 cm and no adverse response after 12 weeks to a test treatment with the pulse dye laser at a fluence of 6.25–6.5 J cm$^{-2}$.

### STUDY DESIGN

The design of the study was organized so that each patient could act as their own control. In order to facilitate this, hollow adhesive templates (0.1 cm thick) were made with internal dimensions of 3×1 cm. Three of these were then attached to the

Accepted for publication: November 6, 1996.

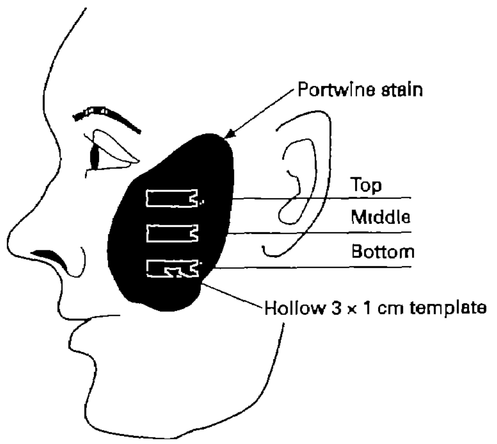

*Figure 1* Positioning of templates for facial portwine stain.

portwine stain area as shown in figure 1. Thereafter, 1 g of each formulation was applied, in a random manner, to the interior of each template. All three templates were then covered with an occlusive dressing and left for 1 h. At the end of this period all three formulations were removed from the portwine stain and the area wiped clean. Six pulses of the laser were then given within each treated area and the pain response noted immediately by the patient using visual analogue (VAS) and verbal rating (VRS) scores.

### PAIN ASSESSMENT

We used both VAS and VRS scores for assessment of pain. With the former, patients were asked to mark a point on a 10-cm horizontal line that corresponded to the degree of pain they felt immediately after each treatment. One end of the line represented no pain while the other was designated as very painful. Four categories of VRS pain scoring were used; 1=no pain, that is complete anaesthesia; 2=very slight pain (almost complete anaesthesia); 3=moderate pain (some anaesthesia has occurred); 4=very painful (no apparent anaesthesia). For statistical purposes scores 1 and 2 were considered clinically acceptable whereas a score of 3 or 4 implied that the treatment had been unsuccessful. VAS data were analysed by ANOVA and detailed comparisons were undertaken by the Scheffé test. In contrast, VRS results were analysed using the chi-square method in the form of a 2×3 contingency table.

### LASER TREATMENT

All patients were treated using a Photogenica V pulse dye laser (Cynosure). Test treatments consisting of a few pulses with the 5 mm spot at fluences of 6.25–6.5 J $cm^{-2}$ were undertaken and the patient reviewed at 12 weeks. If no adverse effects had occurred after this period then the patient received 6 pulses at a consistent fluence of 6.25–6.5 J $cm^{-2}$ applied to the centre of each template.

## Results

VAS data from the 29 patients are shown in figure 2. Details of the VRS results, showing the distribution of all pain scores, are illustrated in figure 3. In contrast, grouping of pain scores 1 and 2, and 3 and 4 are shown in figure 4. Statistical analysis of the data represented by figure 2, using ANOVA, indicated that there was a significant difference between the formulations ($P<0.001$). More detailed analysis, using the Scheffé multi-comparison method, indicated that both amethocaine and EMLA were

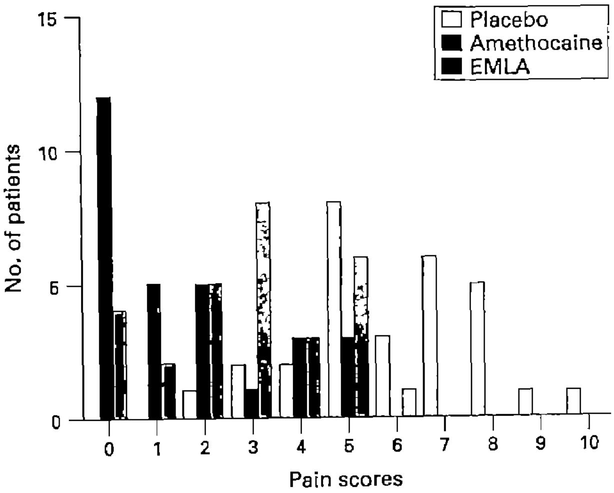

*Figure 2* VAS pain scores for the 29 patients in the three groups.

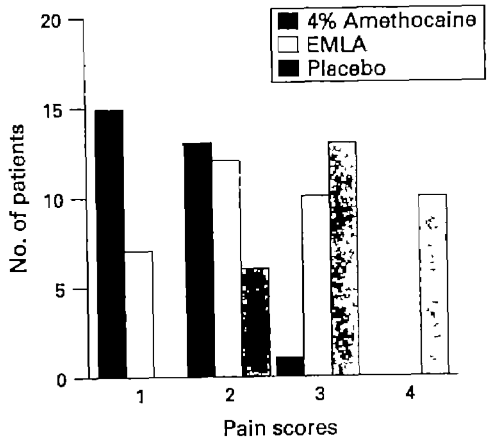

*Figure 3* Number of patients in each VRS pain score group.

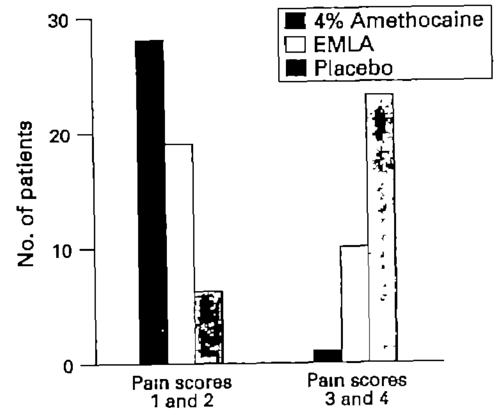

*Figure 4* Number of patients with clinically acceptable percutaneous local anaesthesia (VRS 1 and 2) and clinically unacceptable anaesthesia (VRS 3 and 4).

*Table 1* 2×3 contingency table for chi-square analyses of VRS data

| | 4% Amethocaine | EMLA | Placebo | Total |
|---|---|---|---|---|
| Clinically acceptable anaesthesia | 28 | 19 | 6 | 53 |
| Clinically unacceptable anaesthesia | 1 | 10 | 23 | 34 |
| Total | 29 | 29 | 29 | 87 |

significantly better than placebo in producing percutaneous local anaesthesia ($P<0.001$). This test also demonstrated that the amethocaine-based formulation was more effective than EMLA in reducing pain ($P<0.05$).

The results illustrated in figure 4 are presented in the form of a 2×3 contingency table (table 1). Statistical analyses of these data using the chi-square method indicated that the formulations tested were not equivalent ($P<0.001$). More detailed examination showed that both active preparations were better than placebo ($P<0.001$) and that 4% amethocaine was significantly better than EMLA ($P<0.005$).

## Discussion

The purpose of the present study was to evaluate pain reduction associated with the use of the pulse dye laser when treating portwine stains. However, pain is a subjective phenomenon and although sensory thresholds for pain vary little between individuals, the tolerance level varies considerably between cultures, individuals and even in the same person at different times.[3] This occurs because the subjective intensity of pain depends not only on the extent of the stimulus but also on the degree to which it occupies the subject. Redirection of attention can weaken the sensation and, in extreme conditions such as the stress of an accident or hypnosis, can abolish it .[4] Because of the difficulties in assessing pain, we used two different types of pain measurement—VAS and VRS. The results shown in figure 2 demonstrated typically the variety of responses obtained from VAS assessment. However, it can be seen that the highest individual score for either of the active preparations was 6 while almost 50% of the placebo responses exceeded this. One patient had a maximum painful score (10) for placebo. At the other end of the scale we observed that the amethocaine-based formulation gave more 0 scores than EMLA. It is clear from the statistical analyses of the data that not only were both active preparations better than placebo but that the amethocaine-based formulation was superior to EMLA.

Analyses of the verbal descriptor score showed a similar trend. A particular advantage in using this technique was that it allowed distinction between clinically acceptable (pain scores 1 and 2) or unacceptable (pain scores 3 and 4) topical anaesthesia. Amethocaine accounted for most patients in the pain score 1 category (15) (fig. 3); less than 25% of EMLA-treated patients were in this category. Approximately the same number of patients had a pain score of 2 when either amethocaine or EMLA was used. However, although only one individual had a pain score of 3 for the amethocaine formulation, 10 EMLA-treated patients had this score. No individual scored 4 for either active preparation. Although none of the placebo-treated patients had a pain score of 1, six scored 2 (i.e. clinically acceptable anaesthesia) and approximately 33% scored 3. These results indicated a placebo response but both active formulations were significantly better than placebo. Previous experience has shown that there is almost no placebo response when trained volunteers are used, that is individuals are pretreated with the active formulations so that they can assess the sensation of percutaneous local anaesthesia before taking part in the formal clinical study.[2 5] Although both the VAS and VRS methods gave the same results (after statistical analyses) the VRS data were more highly significant. In a previous study, Ashinoff and Geronemus[1] examined the effects of EMLA on the efficacy of pulse dye laser treatment of portwine stains. The application time for EMLA was the same as in this study and although they claimed that adequate anaesthesia was attained, no quantitative data were reported to substantiate these claims. However, they concluded that the use of this formulation did not appear to adversely influence the efficacy of the pulse dye treatment.

It has been reported previously that 4% amethocaine was more effective than EMLA in reducing the pain of venepuncture.[2 5] This was, perhaps, not surprising considering the *in vitro* penetration characteristics of both preparations. It has been reported that approximately the same amount of amethocaine penetrated human skin from a 4% amethocaine formulation as did prilocaine and lignocaine from EMLA.[6] If this occurred *in vivo* then it would be expected that the amethocaine-based formulation would be more effective as the drug is approximately four times more potent than either prilocaine or lignocaine.[7]

The results of this study indicated clearly that even using the recommended application period of 1 h for EMLA did not appear to be sufficiently long to provide clinically acceptable percutaneous topical local anaesthesia in approximately 33% of patients (fig. 4). In contrast, 4% amethocaine provided satisfactory anaesthesia in all but one patient. A logical progression of the research would be to examine the effects of shorter application times for the amethocaine formulation as it has been demonstrated previously that a 30–40-min contact period was suitable for venepuncture.[2]

LABORATORY INVESTIGATIONS

# Anaesthetic potency of inhalation agents is independent of membrane microviscosity

R. I. NORMAN, R. HIRST, B. L. APPADU, M. MCKAY, P. BRADLEY, R. GRIFFITHS AND D. J. ROWBOTHAM

## Summary

The decrease in membrane microviscosity of erythrocyte ghosts in the presence of clinically relevant concentrations of seven inhalation anaesthetic agents was studied using fluorescence polarization anisotropy of the membrane incorporated fluorescent probes 1,6-diphenyl-1,3,5-hexatriene and 1-[4-trimethylammoniumphenyl]-6-phenyl-1,3,5-hexatriene. All anaesthetic agents produced a dose-dependent decrease in anisotropy of both probes, indicating decreased membrane microviscosity. The reduction in anisotropy measured at the minimum alveolar concentration ($ED_{50}$) for anaesthesia was related inversely to the anaesthetic potency of the agent and was directly proportional to the hypothetical concentration of agent in the membrane calculated from lipid–water partition coefficients. These findings do not support the hypothesis that volatile anaesthetic agents act by increasing membrane microviscosity of the bulk lipid bilayer to produce anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 290–295).

**Key words**
Measurement techniques, anisotropy. Potency, anaesthetic, MAC. Anaesthetics volatile. Theories of anaesthetic action, molecular.

The mechanism of action of inhalation anaesthetics remains unknown even though these agents are used widely in clinical practice. The anaesthetic potency of the volatile agents is correlated most closely with their solubility in non-polar solvents and lipid.[1–5] It has been implied from this relationship that volatile anaesthetic agents may act to alter neuronal membrane function.[3–5] This could occur either through a generalized perturbation of neuronal membrane bilayer structure, by non-specific interaction of membrane dissolved agents with bilayer lipids or by direct modification of neuronal membrane protein activity by interaction with specific hydrophobic binding sites on sensitive proteins. A variety of changes in membrane dynamic properties in the presence of volatile agents have been demonstrated by various biophysical techniques and include increased rotational motion, decreased phase transition temperature, decreased surface viscosity, weakened binding of interfacial water, volume expansion and competition of membrane hydrogen bonds (reviewed by Aloia, Curtain and Gordon[6]). Many of these phenomena have been observed at supra-clinical anaesthetic concentrations and it remains to be determined if any of these perturbations in membrane dynamic properties are relevant to the process of anaesthesia.

The activity and kinetics of membrane-bound enzymes and carrier proteins can be markedly affected by the fluidity of the lipid phase of the membrane.[7] Several neuronal protein activities have been reported to be sensitive to the presence of volatile agents[8–13] and some of these could be involved in the mechanism of anaesthesia. Modification of membrane dynamic properties by volatile anaesthetic agents may be sufficient to transduce the anaesthetic effect of agents in the nervous system. For example, a link between membrane lipid order and sodium channel activity has been proposed from a strong linear relationship between voltage-dependent uptake of $^{24}Na^+$ into isolated mouse brain synaptosomes and the decrease in fluorescence polarization of membrane incorporated probes, 1,6-diphenyl-1,3,5-hexatriene (DPH) and 1-[4-trimethylammoniumphenyl]-6-phenyl-1,3,5-hexatriene (TMA-DPH).[14] By analogy, it has been suggested that changes in protein function induced by membrane dynamic changes, such as the sodium channel, perhaps in conjunction with alterations in other synaptic processes, could result in modified membrane conductance or synaptic transmission and transduce the anaesthetic effect of membrane dissolved agents.[3–5]

If the primary action of the inhalation anaesthetics involves alteration of a property of the lipid bilayer to transduce the effect of agent in the membrane at a functional level, it would be predicted that when tested at equipotent concentrations for anaesthesia the volatile agents may be expected to produce the

same degree of perturbation in that variable. Although not all biological membranes would be involved in transducing the anaesthetic effect, anaesthetic perturbation of membrane dynamics would be expected to be universal. To test this hypothesis, anaesthetic-induced increases in erythrocyte membrane microviscosity produced by clinically relevant concentrations of seven volatile anaesthetic agents were investigated to allow the degree of membrane perturbation at the $ED_{50}$ for anaesthesia for the agents to be determined. Probes studied were DPH, which incorporates into the core hydrophobic region of the lipid bilayer, and TMA-DPH, which localizes in the outer regions of the lipid bilayer by virtue of the cationic trimethylammonium group.[15] These probes intercalate between membrane lipid molecules and the fluorescence polarization anisotropy reports on the restriction of movement of the probe molecule and thus reflects largely the rotational movement of the probe in the membrane. The greater the polarization of the fluorescent emission in response to a polarized excitation the more restricted is the probe in the membrane. Thus fluorescent polarization anisotropy reports on the membrane microviscosity in the environs of the probe.

## Materials and methods

DPH and TMA-DPH were obtained from Molecular Probes Inc. (Eugene, Oregon, USA). Anaesthetic agents were obtained as follows: desflurane was a gift of Pharmacia (St Albans, Hertfordshire, UK), halothane and trichloroethylene were from ICI Pharmaceuticals (Macclesfield, Cheshire, UK), isoflurane and enflurane were from Abbott Laboratories Ltd (Maidenhead, Berkshire, UK), methoxyflurane was from C-Vet (Bury St Edmunds, Suffolk, UK) and nitrous oxide from BOC Ltd (Derby, Derbyshire, UK). Air and oxygen were from BOC Ltd. All other reagents used were of the highest grade available.

### ERYTHROCYTE GHOST MEMBRANES

Venous blood samples were collected from 10 healthy volunteers into tubes containing ethylenediaminetetraacetic acid as anticoagulant. Plasma and the buffy coat were removed after centrifugation at 1900 x g for 10 min at 4°C. Erythrocyte ghost membranes were prepared as reported previously[16] and stored at −20 °C until use.

### MEMBRANE MICROVISCOSITY MEASUREMENTS

Erythrocyte ghost membranes, 100 μg of protein $ml^{-1}$ in 1 ml of Tris-HCl 10 mmol $litre^{-1}$ (pH 7.4), were incubated in a thermistor-controlled water bath at 37±0.1 °C and volatile anaesthetic agents delivered at the required concentration from laser refractometer calibrated vaporizers (Ohmeda TEC (0–2% trichloroethylene; 1–3% methoxyflurane; 0–5% halothane; 0–4% isoflurane; 0–4% enflurane) or TEC 6 (0–20% desflurane)) via a manifold of 10 outlets, each delivering humidified air 60 ml $min^{-1}$ to each sample. The deadspace over each sample was 11 ml. Carrier gas flow through the vaporizers was 2 litre $min^{-1}$ and any excess gas not delivered to experimental tubes was exhausted to the atmosphere. The time taken for each agent to reach stable equilibrium in the aqueous phase was determined in preliminary experiments by following the decrease in DPH and TMA anisotropy with gas delivery at the lowest concentration of each agent to be studied until steady state anisotropy was attained (not shown). Equilibration times were confirmed at approximate MAC concentrations of agent delivered by gas chromatographic analysis using a Perkin-Elmer 8410 gas chromatograph[17] (table 1). Volatile agents (0.2% trichloroethylene, 0.5% methoxyflurane, 0.75% halothane, 1.25% isoflurane and 1.7% enflurane) were delivered for various times (0–60 min) to samples containing 100 μg of erythrocyte ghost membrane protein in 1 ml of Tris-HCl 10 mmol $litre^{-1}$ (pH 7.4). Aliquots (100 μl) were mixed with n-heptane 100 μl (halothane, isoflurane, enflurane) or toluene 100 μl (trichloroethylene, methoxyflurane) in glass vials on ice. The vials were sealed to prevent evaporation before analysis. The non-aqueous phase was injected onto a 30-m DB17 megabore column under the following conditions: injection temperature 120 °C; oven temperature 90 °C; flame ionization detector at 120 °C. The amount of anaesthetic in each sample was determined from the peak height against a standard curve for the agent. All experiments in which polarization anisotropy was measured were performed under steady state conditions to ensure equilibration of the anaesthetics. Pre-equilibration was for 15 min for enflurane, halothane, isoflurane and desflurane, and 60 min for methoxyflurane and trichloroethylene. Nitrous oxide was delivered with oxygen from a Boyles anaesthetic machine for 15 min. Control samples were exposed to air or oxygen only, as appropriate, for the same period.

DPH (in tetrahydrafuran) and TMA-DPH (in dimethylformamide) were added to erythrocyte ghost membranes to final concentrations of 0.5 and 5 μmol $litre^{-1}$, respectively, and incubated for 30 min at 37 °C with gas delivery as before. Addition of solvent from the stock solution never exceeded 0.05%. Fluorescence polarization anisotropy, as a measure of the degree of depolarization of the emitted signal, was measured in duplicate at 37 °C using a Perkin-Elmer LS50 luminescence spectrofluorimeter. Excitation and emission wavelengths were 365 nm and 456 nm. Background fluorescence from unlabelled membrane samples, which was always less than 3% of the total signal, was subtracted from measurements in which probes were incorporated. All measurements were made in duplicate. Under vertical polarized light excitation (subscript V), fluorescence polarization anisotropy was defined by the equation:

$$r=\frac{(I_{\parallel}-I_{\parallel}{}^{S})_V-G(I_{\perp}-I_{\perp}{}^{S})_V}{(I_{\parallel}-I_{\parallel}{}^{S})_V+2G(I_{\perp}-I_{\perp}{}^{S})_V}$$

with a correcting grating factor, to correct for differences in instrument sensitivity for emitted polarized light in the parallel and perpendicular planes, measured on each sample of:

$$G=\frac{(I_{\parallel})_H}{(I_{\perp})_H}$$

where subscript H=horizontal polarized light excitation, and subscripts || and ⊥=components of the emitted light, parallel and perpendicular to the direction of polarization of the excitation beam. Superscript S=contribution of scattered light determined for an unlabelled reference sample of the same composition. Experiments were performed on erythrocytes from 4–10 subjects for each concentration of anaesthetic studied.

### PROTEIN DETERMINATION

Protein concentration was measured by the method of Lowry and colleagues.[18]

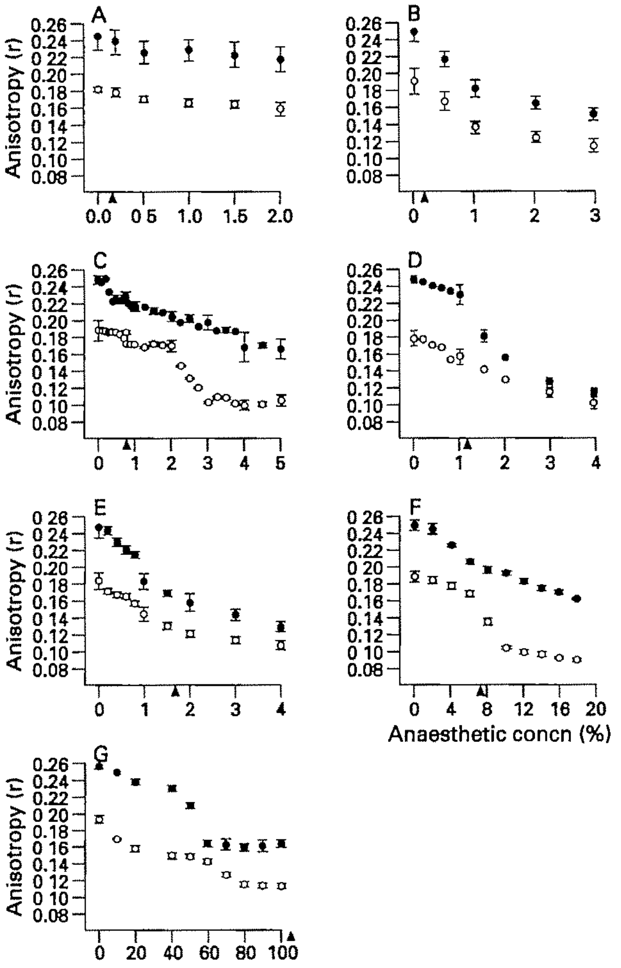

*Figure 1* Dose–response relationships between the fluorescence polarization anisotropy of membrane incorporated DPH (○) and TMA-DPH (●) and the concentration of volatile anaesthetic. A: Methoxyflurane; B: trichloroethylene; C: halothane; D: isoflurane; E: enflurane; F: desflurane; and G: nitrous oxide. Values of anisotropy are mean (SD). Experiments were performed on erythrocytes from 4–10 subjects for each concentration of anaesthetic. The minimum alveolar concentration (MAC) of each agent is shown by the arrow head. MAC values used were: methoxyflurane, 0.16%,[19] trichloroethylene, 0.17% (calculated),[20] halothane, 0.74%,[19] isoflurane, 1.15%,[21] enflurane, 1.68%,[22] desflurane, 7.25%[23] and nitrous oxide, 104%.[24]

## Results

Maximum concentrations of agents used in this study did not alter the wavelength of emission maxima or affect the intensity of emission of membrane incorporated probes in the analyses of fluorescence spectra. We conclude that depolarization measured in the presence of anaesthetic agents was a result of membrane disruption and not alteration of fluorescence life-time by quenching.

A dose-dependent decrease in the anisotropy of both DPH and TMA-DPH was observed over the clinically relevant range of concentrations studied for each agent (fig. 1). The shapes of the dose–response curves varied with each agent and with the distribution of the fluorophore in the membrane.

The ability of equipotent concentrations of agents

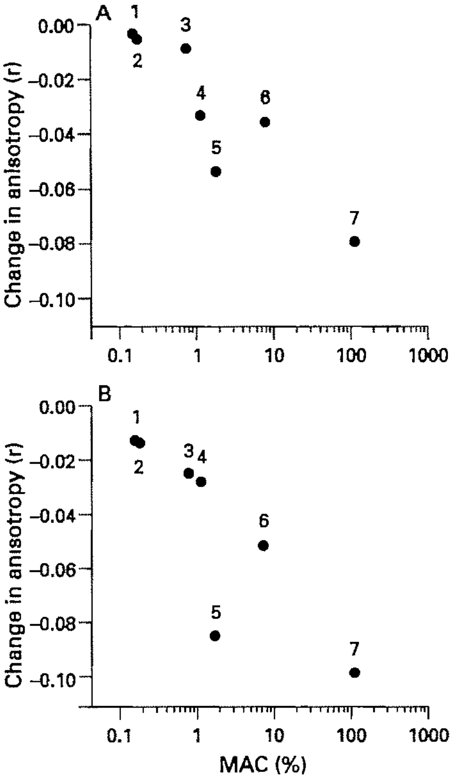

*Figure 2* Relationship between the change in fluorescence polarization anisotropy of erythrocyte ghost incorporated DPH (A) and TMA-DPH (B), measured at the minimum alveolar concentration (MAC) of the delivered agent, and anaesthetic potency (MAC). Anaesthetic agents: 1=methoxyflurane; 2=trichloroethylene; 3=halothane; 4=isoflurane; 5=enflurane; 6=desflurane and 7=nitrous oxide (anisotropy at 100% taken to approximate to MAC of 104%[24]). MAC values used are those given in figure 1.

*Table 1* Equilibration of volatile anaesthetic agents in 1 ml of Tris-HCl 10 mmol litre$^{-1}$ (pH 7.4) containing 100 µg of erythrocyte ghost protein ml$^{-1}$. The concentration of each agent delivered is given in parentheses. Data are mean (SEM) of three individual experiments

| Volatile anaesthetic | Half-life (min) |
|---|---|
| Trichloroethylene (0.2) | 1.8 (0.3) |
| Methoxyflurane (0.5) | 3.0 (0.2) |
| Halothane (0.75) | 1.8 (0.3) |
| Isoflurane (1.25) | 5.5 (1.8) |
| Enflurane (1.7) | 4.9 (0.2) |

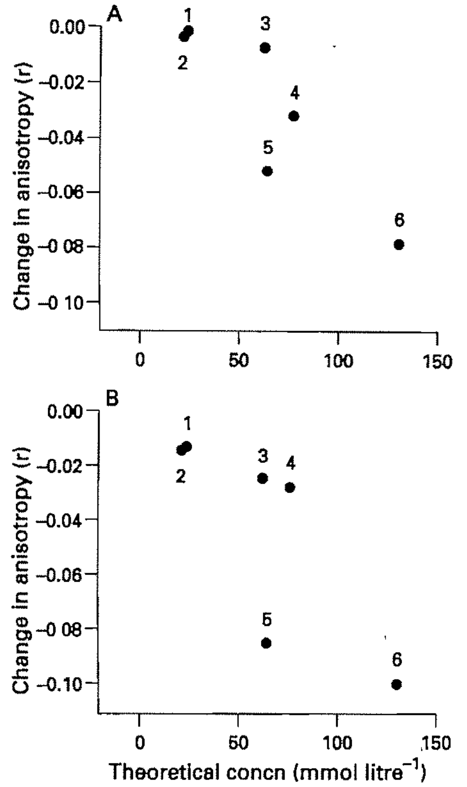

*Figure 3* Relationship between the change in fluorescence polarization anisotropy of erythrocyte ghost incorporated DPH (A) and TMA-DPH (B), measured at the minimum alveolar concentration (MAC) of the delivered agent, and the calculated theoretical concentration of agent in the membrane at MAC. Anaesthetic agents: 1=methoxyflurane; 2=trichloroethylene; 3=halothane; 4=isoflurane; 5=enflurane; 6=nitrous oxide (anisotropy at 100% taken to approximate to MAC of 104%[24]). MAC values used are those given in figure 1.

to perturb membrane microviscosity was assessed by comparing the change in anisotropy of the two membrane incorporated probes at the concentration of agents that produces anaesthesia in 50% of a population, $ED_{50}$ (minimum alveolar concentration, MAC). Values for the change in anisotropy at MAC were derived from the data in figure 1. An inverse relationship between the change in anisotropy of both membrane probes at MAC and anaesthetic potency was observed (fig. 2: DPH, correlation coefficient $r=-0.91$, $P<0.005$; TMA-DPH, $r=-0.85$, $P<0.02$). No other relationship between the potency and degree of membrane perturbation, for example the concentration of agent required to produce a defined change in anisotropy, was identified with either fluorescent probe.

Stable equilibrium between gaseous and aqueous phases at delivered gaseous concentrations of approximately 1 MAC was confirmed for five of the agents (table 1). A theoretical concentration of agent in the erythrocyte membrane at the MAC concentration of delivered gases was calculated,[12] using olive oil–gas partition coefficients where known (unknown for desflurane), and related to the change in anisotropy at MAC for each of the agents (fig. 3). A linear relationship between the change in anisotropy and theoretical membrane concentration was observed for anisotropy determined with the DPH probe (correlation coefficient $r=-0.89$, $P<0.02$) but when TMA-DPH was used as probe this relationship only approached statistical significance ($r=-0.79$, $P=0.06$).

## Discussion

The identity of the primary site(s) of action of volatile anaesthetic agents remains to be determined. There has been much discussion on whether or not an interaction in the membrane bilayer or a direct interaction with hydrophobic sites on target proteins is responsible for anaesthesia (reviewed in Aloia, Curtain and Gordon,[6] Miller,[8] Koblin[9] and Franks and Lieb[12 13]). Polarization anisotropy of the membrane incorporated fluorescent probes DPH and TMA- DPH in the presence of clinically relevant concentrations of volatile agents suggested that decreased membrane microviscosity is linked to changes in functional properties of the membrane.[14 25] To test if there is a relationship between anaesthetic potency and the ability of volatile anaesthetic agents to produce membrane perturbation, reflected by polarization anisotropy of membrane incorporated probes, the change in anisotropy of the probes DPH and TMA-DPH was investigated in this study for a range of volatile anaesthetic agents at clinically relevant concentration ranges. The erythrocyte membrane was used as a simple model biological membrane system with a defined composition and devoid of organelle membranes of varying composition that could have complicated interpretation. Although the magnitude of changes produced in the erythrocyte membrane may be quantitatively different, this membrane system would be expected to mirror changes that occur in other membranes that may have a more direct involvement in the mechanism of anaesthesia.

Using DPH and TMA-DPH to probe the core and outer regions of the bilayer, respectively,[15] we found that clinical concentrations of all agents produced a decrease in anisotropy consistent with decreased membrane microviscosity. The different shapes of the dose–response curves for alteration of membrane microviscosity obtained both for different agents and with respect to localization of the probe in the bilayer suggested complex and non-uniform interactions of the agents within the membrane. Contrary to the proposed hypothesis that equipotent clinical concentrations of volatile anaesthetics would produce a similar degree of membrane perturbation, the most potent anaesthetic agents produced the least change in anisotropy of probes at MAC concentrations. This series of observations indicates that there is no direct relationship between the ability of an agent to alter the anisotropy of membrane probes and anaesthetic potency and argues against a role for disruption of bulk phase membrane microviscosity in the transduction of the effect(s) of volatile anaesthetic agents to membrane mechanisms. These observations further suggest that links between membrane microviscosity and membrane function identified previously[14 25] are unrelated to anaesthetic action.

Dissociation of membrane perturbing effects and anaesthetic mechanism has been suggested previously in a study comparing the actions of

2-[2-methoxyethoxy]-ethyl 8-[cis-2-n-octylcyclopropyl]-octanoate ($A_2C$) and benzyl alcohol.[26] In common with benzyl alcohol, i.v. administration of $A_2C$ was found to perturb brain membranes but, unlike benzyl alcohol, $A_2C$ did not produce either intoxication or anaesthesia in mice. Both $A_2C$ and benzyl alcohol were found to inhibit [$^{35}$S]t-butylbicyclophosphorothionate (TBPS) binding and reduce muscimol- stimulated $^{36}Cl^-$ influx into brain vesicles at the same concentrations that reduced membrane order. However, at lower concentrations benzyl alcohol, but not $A_2C$, stimulated muscimol-activated $^{36}Cl^-$ influx. A two-site model was proposed in which the "perturbant" site responsible for decreased $^{36}Cl^-$ uptake was proposed to be distinct from an "anaesthetic" site responsible for augmentation of $^{36}Cl^-$ flux and anaesthesia.

From the inability to detect membrane perturbations at clinically relevant concentrations of volatile agents using several biophysical techniques,[27–30] it has been argued that the mechanism of anaesthesia of these agents does not involve acting as hydrophobic solutes to produce non-specific perturbation of bulk phase membrane properties and, hence, membrane protein function. Such conclusions presuppose that the chosen biophysical variable investigated reflects any membrane action of an anaesthetic, that a change in properties is observed within the time scale of the measurement and that the variable is sufficiently sensitive to demonstrate an interaction. As important as showing absence of anaesthetic effect at clinical concentrations is investigation of the significance of anaesthetic-induced membrane perturbations that have been reported at clinically relevant concentrations of volatile agents.[14 25] The inverse relationship between the ability to perturb membrane microviscosity and anaesthetic potency observed in this study suggests that links between membrane perturbation and membrane protein function reported previously[14 25] may be secondary phenomena, reflecting the presence of the anaesthetic molecules in the membrane rather than perturbations of relevance to the mechanism of anaesthesia.

As measurements were made at steady state between the gaseous and aqueous phases we were able to calculate a theoretical concentration of each agent in the lipid phase using olive oil–gas partition coefficients. Partition coefficients into lipid systems related to a phospholipid bilayer were not known for enough of the agents to allow this relationship to be calculated for a more representative lipid phase. Although partitioning of gases into olive oil and the erythrocyte membrane is unlikely to be identical, a proportionality in solubility between the two systems would be expected. Despite the differences in chemical structure between the anaesthetics, the change in anisotropy at the MAC concentration was proportional to the calculated theoretical concentration of agent in the lipid phase and, hence, the relative number of molecules of anaesthetic in the lipid bilayer. This correlation was highly significant with the DPH probe but only approached statistical significance for the TMA-DPH probe. Although several assumptions have been made in these calculations, it would appear that membrane microviscosity changes in the presence of volatile anaesthetic agents simply reflect the presence of anaesthetic molecules in the lipid membrane and are unrelated to the mechanism of anaesthesia.

In conclusion, our results are inconsistent with a role for perturbation in membrane microviscosity in the mechanism of anaesthesia of volatile agents. While perturbation of the dynamic properties of the bulk phase of the membrane may be unimportant, the ability of anaesthetic agents to dissolve in membrane bilayers may still prove to be important in their action.

# Effect of propofol on isolated human omental arteries and veins

S. M. WALLERSTEDT AND M. BODELSSON

## Summary

To elucidate the effect and mode of action of propofol on human vascular smooth muscle tension, we have investigated the effect of propofol alone and the effect of propofol on contractions induced by U46619, KCl and caffeine on isolated human omental vessels. Propofol $10^{-3}$ mol litre$^{-1}$ induced contractions in both arteries and veins attenuated the contraction elicited by U46619, KCl and caffeine in a concentration-dependent manner. The threshold concentrations for the effect of propofol in the artery were: $10^{-5}$ mol litre$^{-1}$ (U46619, caffeine) and $10^{-4}$ mol litre$^{-1}$ (KCl); and in the vein, $10^{-5}$ mol litre$^{-1}$ (U46619) and $10^{-4}$ mol litre$^{-1}$ (KCl, caffeine). We conclude that propofol at lower concentrations appeared to primarily attenuate contraction involving release of cellularly sequestered calcium. At higher concentrations ($>10^{-4.5}$ mol litre$^{-1}$), propofol appeared to affect contraction involving extracellular or intracellular calcium fluxes similarly. (*Br. J. Anaesth.* 1997; **78**: 296–300).

**Key words**
Anaesthetics i.v, propofol. Arteries, contraction. Veins, contraction. Ions, calcium.

Anaesthesia with propofol is accompanied by a reduction in arterial pressure.[1–4] This has been suggested to be caused by a decrease in either cardiac output (CO)[5], systemic vascular resistance (SVR),[6–10] or both.[1] The decrease in CO could be a result, at least in part, of a propofol-induced increase in venous capacitance.[4 11] Earlier studies suggest that the underlying mechanisms include both depression of sympathetic outflow[12 13] and a direct effect on the blood vessels or heart.[13]

An understanding of the mechanisms of the direct action of propofol on the blood vessel wall may be useful in the development of new anaesthetic agents with less tendency to induce hypotension during anaesthesia. Previous studies on vascular specimens have suggested that propofol decreases the contractility of vascular smooth muscle by modulating free cytosolic calcium availability. In the rat aorta,[14] atria and portal vein[15] and rabbit mesenteric arteries and veins,[16] propofol has been reported to act as a calcium channel antagonist and in isolated canine coronary arteries, propofol may act as a calcium channel agonist.[17] In the porcine coronary artery, propofol at low concentrations inhibits calcium influx, while propofol at higher concentrations ($10^{-4}$ mol litre$^{-1}$) also inhibits intracellular calcium release.[18] The relevance of the results from these experiments in humans is unclear. The aim of this study was to investigate the direct effects of propofol and the effect of propofol on contractions involving influx of extracellular calcium or release of cellularly sequestered calcium in isolated human omental artery and vein.

## Materials and methods

The study was approved by the Ethics Committee of the University of Lund.

Macroscopically normal segments of human omental arteries and veins were obtained from 36 patients, aged 29–88 yr (median 61 yr), undergoing abdominal surgery. Patients with endocrine tumours, abdominal infections and previous radiotherapy were excluded. The male/female ratio was 0.7. Experiments were performed within 48 h. The vessels, after being dissected free from fat and connective tissue, were stored in aerated Krebs–Ringer solution (KRS, composition see below) at +4 °C. Vessels were cut into 2–4-mm long ring segments and placed in 2-ml tissue baths on two L-shaped hooks, one of which was attached to a Grass FTO3C force displacement transducer for isometric measurement of tension. Vessel tension was recorded on a Grass polygraph model 7b. The baths were maintained at 37 °C and contained KRS, which was aerated continuously with 88.5% oxygen and 11.5% carbon dioxide, to give pH 7.4, $P\text{CO}_2$ 5.0 kPa and $P\text{O}_2$ approximately 40 kPa.

The artery and vein segments were stretched gradually to a resting tension of 6 mN during a 60–90-min equilibration period, to obtain the previously determined optimal resting tension level. After the equilibration period, KCl 90 mmol litre$^{-1}$ was added to the baths repeatedly (2–4 times), each time followed by washout, until consistent contractions were elicited. For each vessel segment, the greatest contraction elicited was used as a contraction reference. Contractile responses are given as percentages of this contraction reference.

In the first series of experiments, propofol was added cumulatively ($10^{-9}$–$10^{-3}$ mol litre$^{-1}$) to the

---

organ baths at 10-min intervals to allow the segments to respond to each concentration. Every 20 min KRS was changed. Control experiments with the corresponding concentrations of the propofol solvent dimethylsulphoxide (DMSO) were performed in parallel.

In the second series of experiments, the dependence of extracellular calcium for the action of KCl and the stable thromboxane $A_2$ analogue, U46619, was determined. The two contractors (KCl 90 mmol litre$^{-1}$ and U46619 $10^{-10}$–$10^{-5}$ mol litre$^{-1}$ in log units cumulatively) were added to vessel segments in organ baths containing either KRS or calcium-free KRS ($Ca^{2+}$-free KRS, composition see below) and the resulting contraction recorded.

In the third series of experiments, we investigated the influence of propofol on contractions induced by KCl in KRS and U46619 in $Ca^{2+}$-free KRS. Tissues were preincubated with a propofol concentration of either $10^{-6}$, $10^{-5.5}$, $10^{-5}$, $10^{-4.5}$, $10^{-4}$, $10^{-3.5}$ or $10^{-3}$ mol litre$^{-1}$ for 10 min. The buffer solution was then changed, the same concentration of propofol was added again, and KCl $10^{-3}$–$10^{-1}$ mol litre$^{-1}$ in 0.5 log units cumulatively or U46619 $10^{-10}$–$10^{-5}$ mol litre$^{-1}$ in log units cumulatively was added. The resulting contraction was recorded. Control experiments with vessel segments exposed to equal concentrations of the propofol solvent DMSO were also performed.

In the fourth series of experiments, we investigated the influence of propofol on the release of cellularly sequestered calcium. Tissues were preincubated with propofol at concentrations of $10^{-5}$, $10^{-4.5}$, $10^{-4}$ or $10^{-3.5}$ mol litre$^{-1}$ for 10 min. $Ca^{2+}$-free KRS was used. The buffer solution was then changed, and the same concentration of propofol was added in addition to caffeine 20 mmol litre$^{-1}$. The resulting contraction was recorded. Control vessels exposed to DMSO were performed in parallel.

### STATISTICAL ANALYSIS

Values are expressed as mean (SEM). The Student's *t* test was used for statistical evaluation. $P<0.05$ was considered statistically significant and only significant differences are given in the text. When similar experiments were performed on more than one segment from the same patient, the mean for each patient was calculated before presentation and statistical analysis. The number of patients is indicated by *n*.

### PHARMACOLOGICAL AGENTS

The following compounds were used: propofol (Research Biochemicals International, RBI); 9,11-dideoxy-11,9-epoxy-methanoprostaglandin $F_{2\alpha}$ (U46619, Sigma); caffeine (KEBO Lab); disodium-calcium EDTA (Sigma); dimethylsulphoxide (DMSO, Sigma); ethylene glycol-bis(β-amino-ethylether) N,N,N',N'-tetraacetic acid (EGTA, Sigma). The compounds were dissolved and diluted in distilled water, except for propofol, which was dissolved in DMSO and diluted in distilled water. Krebs–Ringer solution (KRS) contained (mmol litre$^{-1}$): $Na^+$ 143, $K^+$ 4.6, $Cl^-$ 126.4, $Ca^{2+}$ 2.5, $HCO_3^-$ 25.0, $Mg^{2+}$ 0.79, $SO_4^{2-}$ 0.79, $H_2PO_4^-$ 1.2, glucose 5.5 and EDTA 0.024. The calcium-free Krebs–Ringer solution ($Ca^{2+}$-free KRS) refers to KRS from which $Ca^{2+}$ 2.5 mmol litre$^{-1}$ and $Cl^-$ 5 mmol litre$^{-1}$ were omitted and EGTA 0.1 mmol litre$^{-1}$ was added. To ensure calcium-free solution in the organ baths, the baths were rinsed repeatedly with $Ca^{2+}$-free KRS for 15 min before the experiments.

## Results

When added cumulatively to the vessel segments, propofol was found to alter vessel tension in both artery and vein segments similarly. At concentrations less than $10^{-5}$ mol litre$^{-1}$, no change was seen, but at $10^{-5}$ and $10^{-4}$ mol litre$^{-1}$, vessel tension became increasingly unstable. At $10^{-3}$ mol litre$^{-1}$, contractions of 28 (10) % (artery, $n=3$) and 50 (5) % (vein, $n=3$) were seen. The propofol solvent DMSO, in equal amounts as in the propofol experiments, did not affect vessel tension (fig. 1).

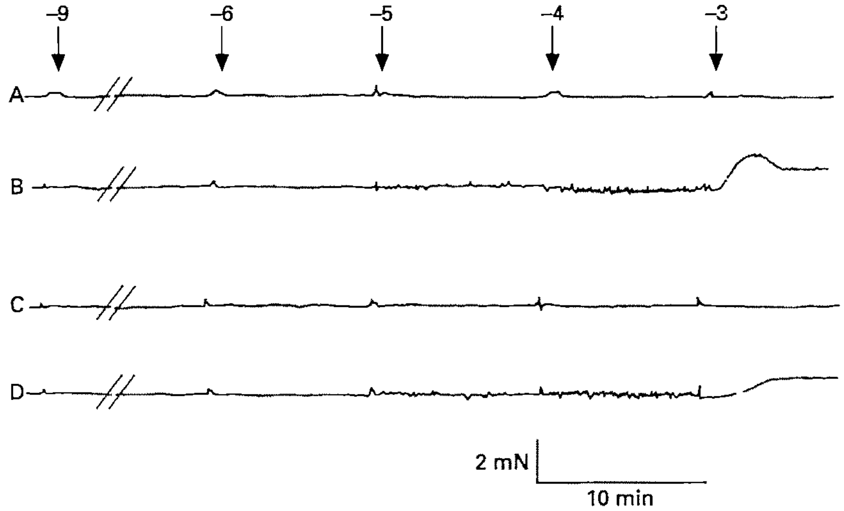

*Figure 1* Tracing of isometric tension in an isolated human omental artery segment in the presence of increasing concentrations of the propofol solvent DMSO (A) and propofol (B), and in a vein segment in the presence of increasing concentrations of DMSO (C) and propofol (D). DMSO was administered in concentrations equal to the concentration of DMSO in the corresponding propofol experiments.

Values are mean (SEM).

KCl contracted vessel segments in organ baths containing KRS. No contraction occurred in segments in baths containing Ca$^{2+}$-free KRS (artery: $n$=3, vein: $n$=3). Contraction induced by KCl was not affected by propofol at concentrations less than $10^{-4}$ mol litre$^{-1}$. At this concentration the contractile response induced by KCl was diminished. In the presence of propofol $10^{-3.5}$ mol litre$^{-1}$ the contractile response was further attenuated. The contraction induced by KCl was abolished in the presence of propofol $10^{-3}$ mol litre$^{-1}$. Artery and vein segments behaved similarly (fig. 2). DMSO, in equal concentrations as in the propofol experiments, did not affect KCl-induced contraction (artery: $n$=3, vein: $n$=3).

U46619 induced similar contractions in artery and vein segments, irrespective of the medium present in the baths (KRS or Ca$^{2+}$-free KRS, data not shown; artery: $n$=5, vein: $n$=3). All subsequent experiments with U46619 were performed in Ca$^{2+}$-free KRS. Propofol at concentrations of $10^{-6}$ and $10^{-5\ 5}$ mol litre$^{-1}$ (not shown, artery: $n$=3, vein: $n$=4) did not affect U46619-induced contraction. At higher concentrations of propofol, the contraction induced by U46619 was attenuated in a concentration-dependent manner and was abolished completely at the highest concentration tested ($10^{-3}$ mol litre$^{-1}$, fig. 3). DMSO, in equal amounts as in the propofol experiments, did not alter U46619-induced contraction (artery: $n$=9, vein: $n$=7).

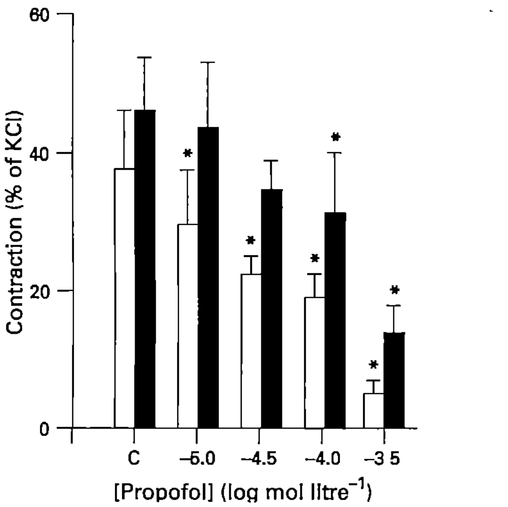

*Figure 4* Effect of propofol on contractions induced by caffeine 20 mmol litre$^{-1}$ in $Ca^{2+}$-free KRS in human omental arteries (□) and veins (■), $n$=6–7. *$P<0.05$ compared with control (C) (Student's $t$ test). Values are mean (SEM).

Caffeine-induced contraction was attenuated by a propofol concentration of $10^{-5}$ mol litre$^{-1}$ (artery) and $10^{-4}$ mol litre$^{-1}$ (vein). At higher concentrations of propofol, contraction was further attenuated (fig. 4).

## Discussion

This study supports the theory that changes in systemic vascular resistance contribute to propofol-induced hypotension, as propofol attenuated KCl-, U46619- and caffeine-induced contractions in human omental arteries. This is consistent with several measurements *in vivo* in both humans[1 6 8–10] and rats.[2] Vein segment contractions were also affected by propofol. This indicates that propofol may interfere with regulation of vessel tone on both the arterial and venous side of the circulation. This is consistent with *in vivo*[4 11] and *in vitro* studies,[19] but it contrasts with the findings of Baraka and colleagues,[8] who could not detect a change in venous reservoir during cardiopulmonary bypass. Different methods being used, for example *in vivo* and *in vitro* studies, and regional and species differences may explain the various findings.

An increase in cytosolic calcium is necessary for smooth muscle contraction. This may be achieved either by influx of calcium via specific channels in the cell membrane, by release of cellularly sequestered calcium or by a combination of these mechanisms. Our study showed that KCl-induced contraction in human omental arteries and veins was totally dependent on influx of extracellular calcium, as KCl-induced contraction was abolished in $Ca^{2+}$-free KRS. In contrast, U46619-induced contraction appeared to be mediated to a major extent via release of cellularly sequestered calcium, as changing KRS to $Ca^{2+}$-free KRS did not alter the concentration–response curve for U46619 in the artery or vein segments.

The lowest concentration of propofol which depressed U46619-induced contraction in $Ca^{2+}$-free KRS in both artery and vein segments was $10^{-5}$ mol litre$^{-1}$. KCl-induced contraction was unaffected by propofol at this concentration and a concentration of $10^{-4}$ mol litre$^{-1}$ was required to attenuate KCl-induced contraction. Thus propofol appeared to be more potent in inhibiting U46619-induced contraction than contractions elicited by KCl. These results suggest that propofol at the lowest effective concentration mainly modulated intracellular calcium release.

U46619 contracts smooth muscle primarily via $IP_3$-mediated calcium release from intracellular stores,[20] while caffeine primarily activates ryanodine receptors, thereby releasing calcium from these stores.[21] Both these mechanisms seem to be functional in vascular smooth muscle cells,[22] but they might not be two distinct processes. In the artery both U46619- and caffeine-induced contractions (i.e. probably both $IP_3$- and ryanodine receptor-mediated calcium release) were inhibited by propofol $10^{-5}$ mol litre$^{-1}$. In contrast, in the vein, propofol at this concentration appeared to interact only with $IP_3$-mediated intracellular calcium release.

Our results cannot easily be extrapolated to the *in vivo* situation. Concentrations of vasoactive compounds at their site of action are difficult to determine. The lowest effective propofol concentration in this study ($10^{-5}$ mol litre$^{-1}$) might be greater than the greatest concentration achieved during anaesthesia (cf. Park, Lynch and Johns[23]). Thus the clinical relevance of these findings remains to be determined.

At propofol concentrations of $10^{-4}$ mol litre$^{-1}$ and higher, contractions induced by all three contractors (U46619, caffeine and KCl) were attenuated. When added cumulatively to resting vessel segments, propofol at a concentration of $10^{-3}$ mol litre$^{-1}$ caused a small contraction. These effects of propofol may not be clinically important.

The study of Kamitani and colleagues[16] suggests that propofol interacts with endothelium-dependent mechanisms. The endothelium may actively interact with contractions in human omental arteries and veins.[24] In this study we have used endothelium intact vessel segments in order not to deviate too much from *in vivo* conditions. This implies that no conclusions can be drawn on the involvement of the endothelium in the action of propofol.

In summary, we have shown that propofol attenuated release of cellularly sequestered calcium in omental arteries and veins, which resulted in reduction in vessel tone. At higher concentrations of propofol a contraction-attenuating effect of a different nature appeared which was non-specific with regard to extra- or intracellular calcium fluxes.

# Differential effects of clonidine and dexmedetomidine on gastric emptying and gastrointestinal transit in the rat†

T. Asai, W. W. Mapleson and I. Power

## Summary

We have studied the effect of clonidine, dexmedetomidine and morphine on gastric emptying and gastrointestinal transit in the rat. In one group, each agonist was injected i.p. in 6–12 male Wistar rats. In another group of rats, yohimbine, naloxone or saline was injected with an agonist. At 30 min, radiolabelled saline 1 ml was infused into the stomach. At 1 h, gastric emptying and gastrointestinal transit were calculated by measuring the radioactivity in the gastrointestinal tract. We found that clonidine and dexmedetomidine strongly inhibited gastrointestinal transit ($ED_{50}$ 0.08 and 0.04 mg $kg^{-1}$, respectively). They also significantly inhibited gastric emptying ($P<0.05$), but the effect was weak (95% confidence intervals for difference from saline 8.2–34.9% with clonidine 1 mg $kg^{-1}$ and 3.4–15.4% with dexmedetomidine 0.03 mg $kg^{-1}$). Morphine strongly inhibited both gastric emptying and gastrointestinal transit ($ED_{50}$ 2.8 and 1.2 mg $kg^{-1}$, respectively). Yohimbine significantly antagonized the inhibitory effects of clonidine and dexmedetomidine ($P<0.05$), whereas naloxone, which significantly antagonized the effect of morphine ($P<0.01$), did not antagonize the effect of either of the other agonists. (*Br. J. Anaesth.* 1997; **78**: 301–307).

**Key words**
Gastrointestinal system, gastric emptying. Sympathetic nervous system, adrenergic agonists.

Delayed gastric emptying may induce several complications during the perioperative period. In critically ill patients, gastric emptying and intestinal transit are often delayed and this delay may cause pulmonary infection and bacterial overgrowth in the gastrointestinal tract.[1]

Opioids have been used widely in the perioperative period and in intensive care units, but they markedly delay both gastric emptying and intestinal transit.[2 3] However, we have been unable to trace any report of the $ED_{50}$ of morphine in inhibiting gastric emptying; therefore, the relative potency of opioids on gastric emptying and intestinal transit is not known.

$Alpha_2$ adrenoceptor agonists, such as clonidine or dexmedetomidine, reduce anxiety, induce sedation and produce analgesia.[4 5] They also decrease the amount of opioid and inhalation agent needed for induction and maintenance of anaesthesia while providing haemodynamic stability.[4 5] $Alpha_2$ agonists produce less respiratory depression, nausea and vomiting or pruritus than opioids.[4 5] For these reasons, the use of $alpha_2$ adrenoceptor agonists as adjuncts to anaesthetics has received much attention recently.[4 5]

There have been several reports on the effects of $alpha_2$ adrenoceptor agonists on gastric emptying, but the results are inconclusive. In some studies, peripherally injected $alpha_2$ adrenoceptor agonists did not delay gastric emptying in rodents.[6–8] In other studies they delayed gastric emptying of liquids in the rat[9] and that of both solids and liquids in the dog.[10] In humans, oral clonidine did not significantly delay gastric emptying of either a solid meal[11] or liquids,[12] whereas lidamidine, which also has an $alpha_2$ adrenoceptor agonist effect, weakly delayed gastric emptying.[13] These differences might have been caused by selectivity of these drugs to receptors other than the $alpha_2$ adrenoceptor.

Dexmedetomidine, the dextro-stereoisomer of medetomidine, is a highly selective $alpha_2$ adrenoceptor agonist.[14] Binding studies have shown that the selectivity of medetomidine to the $alpha_2$ adrenoceptor over the $alpha_1$ adrenoceptor is 5–10 times greater than that of other $alpha_2$ adrenoceptor agonists, such as clonidine and detomidine.[15]

The first aim of this study was to examine the effect of clonidine, dexmedetomidine and morphine on gastric emptying and gastrointestinal transit of liquids in the rat. The second aim was to determine the receptor type involved in the effects of these agonists.

## Materials and methods

We used male Wistar rats, weighing 200–250 g. The study was conducted under the Animal (Scientific

†Presented in part at the Anaesthetic Research Society, Birmingham Meeting, July 11–12, 1996 (*British Journal of Anaesthesia* 1996; 77: 686P).

Procedures) Act 1986 (Home Office Licence PPL 40/954, PPL 40/1397). Before the experiment, rats were housed under standard controlled environmental conditions, with a 12-h light–dark cycle. The animals were fasted for 24 h, but they were allowed free access to water until 20–30 min before the start of the experiment. Each animal was kept individually in a wire-mesh cage to prevent coprophagy during fasting. All experiments were started between 10:00 and 11:00. Dexmedetomidine (Orion-Famos Pharmaceuticals, Finland), clonidine, morphine and yohimbine (Sigma Chemical Co., UK) were prepared freshly on each day of experiment.

A group of six rats was allocated for each set of circumstances. If more than one rat was excluded (see below), another group of six rats was used until a group was completed in which no more than one rat was excluded. Data from the non-excluded rats from all groups for each set of circumstances (the number of rats ranged from 5 to 12) were used. However, we stopped after studying three rats for the highest doses of morphine and dexmedetomidine because of apparent complications (see results).

Gastric emptying and gastrointestinal transit were studied using radiolabelled sodium chromate,[16 17] which is minimally absorbed when infused into the stomach.[17] Clonidine 0.001–1.0 mg $kg^{-1}$, dexmedetomidine 0.0001–0.1 mg $kg^{-1}$, morphine 0.1–30 mg $kg^{-1}$ or saline, in a volume of 1.0 ml $kg^{-1}$, was given i.p. These doses were chosen on the basis of the reported $ED_{50}$ values for the antinociceptive effect of each drug (see discussion).

Thirty minutes later the rats were anaesthetized lightly with halothane. When the rat had become unconscious, saline 1.0 ml containing a radioactive marker (0.5 μCi (18.5 kBq) of chromium as the sodium salt ($^{51}Cr$ as $Na_2CrO_4$)) was given via a metal cannula into the stomach. The rat was allowed to recover from anaesthesia, which usually occurred within a few minutes.

Another 30 min later the rats were killed, the oesophagus just proximal to the gastric fundus and the duodenum just distal to the pylorus were cross-clamped, and the stomach and small intestine were removed. Twelve clamps were applied to the small intestine during gentle removal of the intestine to minimize the movement of contents. The intestine was placed on a ruled template and divided into 10 equal segments. The stomach and segments of intestine were placed into individual counting tubes.

Radioactivity in each segment was measured using an automatic gamma sample counter and counts per minute (cpm) obtained. Each sample was counted twice and mean cpm obtained. To obtain the control total count, 1.0 ml of radiolabelled saline was placed into a tube and the radioactivity counted. If there was chyme in either the stomach or small intestine, data were not used.

Gastric emptying of liquids was calculated as the percentage of radioactivity (cpm) which had entered the small intestine:

$$\%\text{gastric emptying } (\%\text{GE}) = ((\text{total cpm} - \text{stomach cpm}) \,/\, (\text{total cpm})) \times 100$$

From these values, percentage inhibition of gastric emptying was calculated from:

$$\%\text{inhibition of GE} = 100 \times (\text{control } \%\text{GE} - \text{test } \%\text{GE}) \,/\, \text{control } \%\text{GE}$$

where control %GE=mean %GE in the rats that received saline, and test %GE=%GE in each rat that received the test drug.

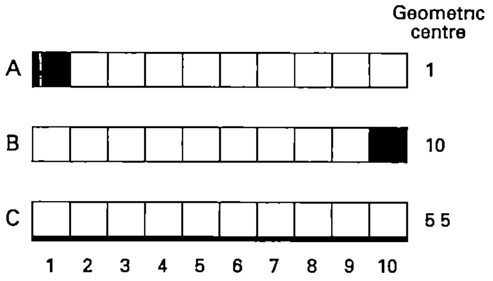

*Figure 1* Three hypothetical examples of the distribution of marker in the 10 segments of the small intestine. The distribution is expressed as "geometric centre" (the centre of gravity) ($=\Sigma(CiSi)/\Sigma Ci$, where Ci=count in segment Si)[16]: A: all the marker is in segment 1, therefore the geometric centre is 1 ($1\times1+0\times2+\ldots+0\times10=1$); B: all the marker is in segment 10, therefore the geometric centre is 10 ($0\times1+\ldots+0\times9+1\times10=10$); C: the marker is evenly distributed throughout the 10 segments, therefore the geometric centre is 5.5 ($0.1\times(1+2+\ldots+10)=5.5$).

Gastrointestinal transit was assessed using the "geometric centre" (the centre of gravity). This was calculated by a modification of a method described by Miller, Galligan and Burks[16] (fig. 1):

$$\text{geometric centre (GC)} = \Sigma(CiSi)/\Sigma Ci$$

where Ci=count in segment Si.

Percentage inhibition of gastrointestinal transit, expressed as the geometric centre (%GC), was calculated from:

$$\%\text{inhibition of gastrointestinal transit} = 100 \times ((\text{control GC} - \text{test GC}) \,/\, \text{control GC})$$

In the second part of the experiment, the receptor type involved in the inhibitory effect of the agonists was studied using yohimbine (an $alpha_2$ antagonist) and naloxone. The initial plan was to inject yohimbine, naloxone or saline with the $ED_{75}$ (see below) of each agonist. However, neither clonidine nor dexmedetomidine inhibited gastric emptying by greater than 50% (see results). Therefore, for clonidine, the $ED_{50}$ for antinociceptive effect (0.15 mg $kg^{-1}$)[18] was used; for dexmedetomidine, the second highest dose (0.03 mg $kg^{-1}$) was used as the $ED_{50}$ for antinociceptive effect in rats was not available. In another group of rats, gastric emptying and gastrointestinal transit after injection of either yohimbine or naloxone alone were studied.

### STATISTICAL ANALYSIS

The Mann–Whitney *U* test was used to compare gastric emptying and gastrointestinal transit between groups of rats which were subjected to different agonists or agonist–antagonist combinations. The values for all doses of clonidine or dexmedetomidine were pooled for this analysis. Either a Wilcoxon-type test for trend[19] (when two doses of an antagonist were used) or the Mann–Whitney *U* test (when one dose of an antagonist was used) was used to examine the effect of either yohimbine or naloxone on the inhibitory effect of agonist. $P<0.05$ was considered significant. The confidence intervals for medians

*Table 1* $ED_{50}$ (mg kg$^{-1}$) of clonidine, dexmedetomidine and morphine on gastric emptying and gastrointestinal transit (with 95% confidence limits). The $ED_{50}$ and upper 95% confidence limit were omitted when they were outside the range of doses used

| | Gastric emptying | Gastrointestinal transit |
|---|---|---|
| Clonidine | — | 0.080 |
| (*n*=41) | (4.6, —) | (0.049, 0.13) |
| Dexmedetomidine | — | 0.039 |
| (*n*=30) | (4.3, —) | (0.027, 0.065) |
| Morphine | 2.8 | 1.2 |
| (*n*=52) | (2.1, 3.8) | (0.87, 1.7) |

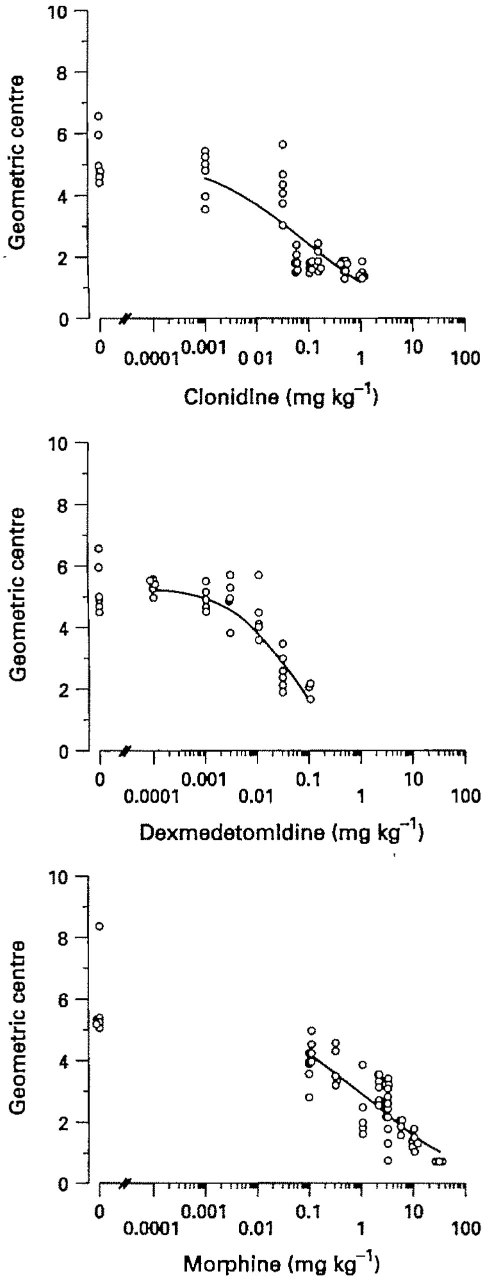

*Figure 2* Effect of clonidine (top), dexmedetomidine (middle) and morphine (bottom) on gastrointestinal transit. Saline 1 ml, containing a radiolabelled marker ($^{51}$Cr), was given 30 min after i.p. injection of drug. Gastrointestinal transit was examined 30 min later. A fitted logit dose–response curve is shown together with the value obtained from each rat (O). Symbols were displaced slightly on the *X* axis if there were similar values for any given dose. Values at zero dose are for the saline control.

were calculated using the SINTERVAL command (sign test) in Minitab Release 8.2 (running on Macintosh LC computer), which shows exact intervals for a stated confidence level close to 95%. Confidence intervals (CI) for the difference in gastric emptying between saline and an alpha$_2$ agonist were also calculated.

The variation in percentage inhibition with the dose of each agent was modelled by fitting a sigmoid logit curve to fractional inhibition against log dose. This was done (see appendix) using the statistical package GLIM (Generalized Linear Interactive

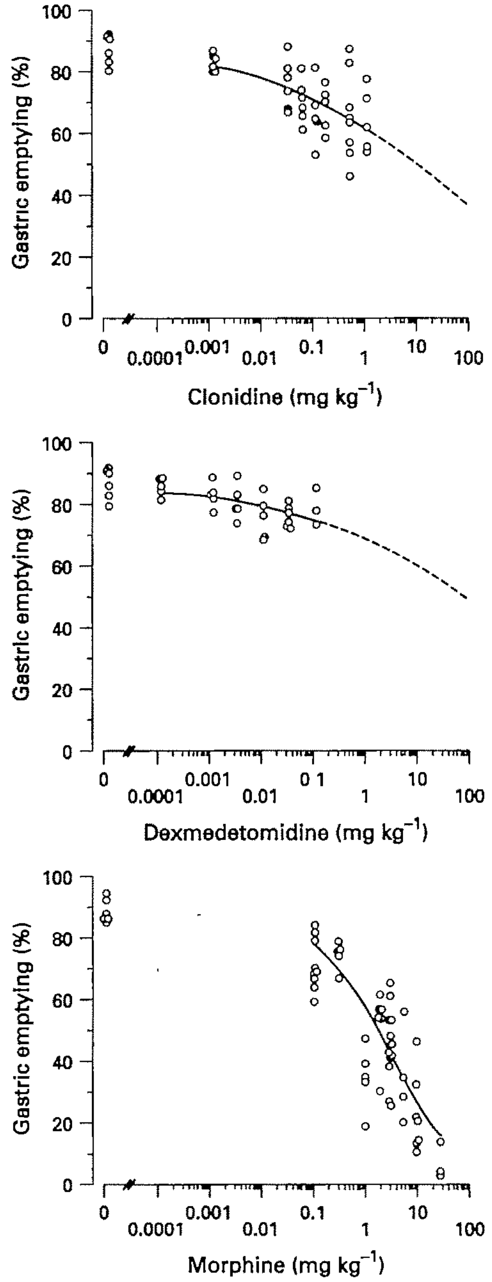

*Figure 3* Effect of clonidine (top), dexmedetomidine (middle) and morphine (bottom) on gastric emptying of a liquid. Saline 1 ml, containing a radiolabelled marker ($^{51}$Cr), was given 30 min after i.p. injection of drug. Gastric emptying was examined 30 min later. A fitted logit dose–response curve is shown together with the value obtained from each rat (O). Symbols were displaced slightly on the *X* axis if there were similar values for any given dose. The extrapolated parts of the curves for clonidine and dexmedetomidine are shown by a broken line. Values at zero dose are for the saline control.

*Table 2* Effect of yohimbine or naloxone on the inhibitory effect of clonidine, dexmedetomidine or morphine on gastric emptying and gastrointestinal transit of saline (median). *P* values were calculated using either the Wilcoxon-type test for trend[18] (when two doses of antagonist were used) or the Mann-Whitney *U* test (when one dose of antagonist was used), and 95% confidence limits (CL) of the difference between rats which received saline and those which received an antagonist are shown. Six to 12 rats were used for each group. [a]Antagonist effect; [b]additive effect

Modelling), version 4,[20] update 8, running on a DEC mainframe computer under the Ultrix operating system (OSF/1 V2.OB). The output from the fitting process provided the information required to calculate $ED_{50}$ and $ED_{75}$ and, using the Fieller equation, the 95% confidence interval (CI) of those doses.[20 21]

## Results

Morphine 30 mg kg$^{-1}$ caused muscle rigidity; therefore, we stopped after studying three rats at this dose. Dexmedetomidine 0.1 mg kg$^{-1}$ caused strong sedation and apparent respiratory depression; therefore, we stopped after studying three rats. Clonidine 1.0 mg kg$^{-1}$ and dexmedetomidine 0.03 mg kg$^{-1}$ caused obvious sedation in all rats.

### GASTROINTESTINAL TRANSIT

Clonidine, dexmedetomidine and morphine inhibited gastrointestinal transit in a dose-dependent manner (fig. 2, table 1).

### GASTRIC EMPTYING

Morphine inhibited gastric emptying in a dose-dependent manner (fig. 3, table 1). In contrast, although clonidine significantly inhibited gastric emptying ($P=0.001$), the inhibitory effect was weak (95% CI for difference from saline 8.2–34.9% at the maximum dose of clonidine, 1 mg kg$^{-1}$) (fig. 3). Dexmedetomidine also weakly, but significantly, inhibited emptying ($P<0.05$; 95% CI for difference from saline 3.4–15.4% at the next-to-maximum dose, 0.03 mg kg$^{-1}$) (fig. 3).

### RECEPTOR TYPE

Yohimbine, an alpha$_2$ adrenoceptor antagonist,[22] significantly antagonized the inhibitory effect of clonidine and dexmedetomidine, but not that of morphine (table 2). Yohimbine itself at the doses used did not significantly affect either gastric emptying or gastrointestinal transit, although the rate of gastric emptying varied considerably after injection of yohimbine 3.0 mg kg$^{-1}$.

Naloxone itself significantly delayed gastric emptying, but not gastrointestinal transit (table 2). Despite its inhibitory effect, naloxone significantly antagonized the inhibitory effect of morphine (table 2). Naloxone did not significantly antagonize the effect of clonidine or dexmedetomidine; in fact, naloxone delayed gastric emptying further (table 2).

## Discussion

### DIFFERENCE IN THE EFFECTS BETWEEN ALPHA$_2$ AGONISTS AND MORPHINE

When the fitted curves for the effect of each drug on gastric emptying and gastrointestinal transit were plotted in terms of percentage of control values (fig. 4), it was apparent that morphine inhibited gastric emptying and gastrointestinal transit to a similar degree, whereas with clonidine and dexmedetomidine, inhibition of gastric emptying was much weaker than that of gastrointestinal transit. The ratio of the $ED_{50}$ values for gastrointestinal transit and

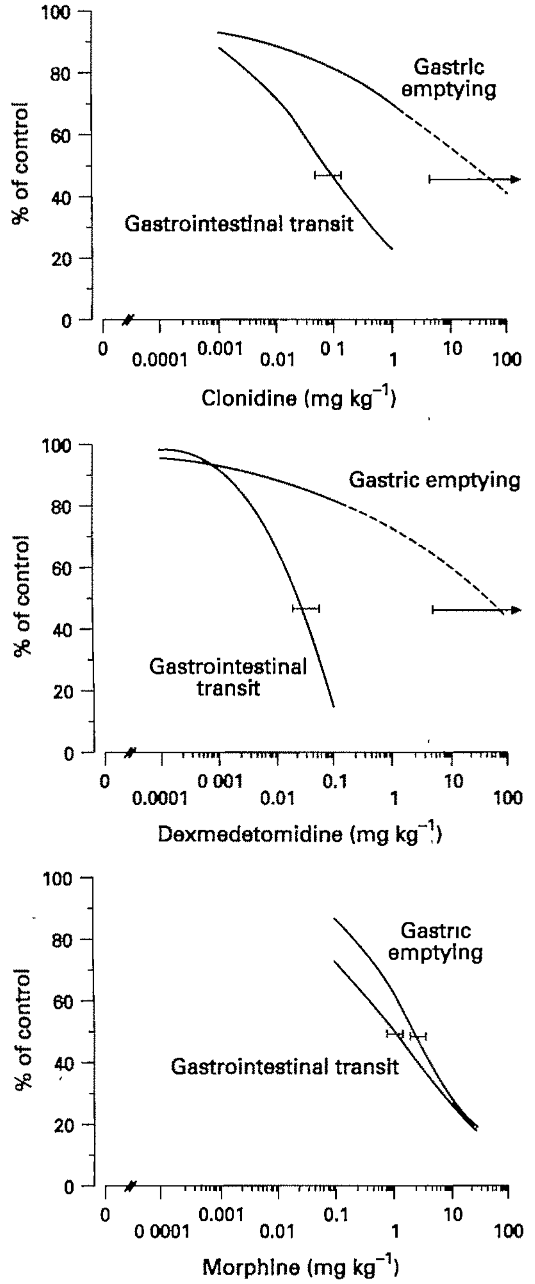

*Figure 4* Percentage gastric emptying and gastrointestinal transit of the control values for clonidine (top), dexmedetomidine (middle) and morphine (bottom). The extrapolated parts of the curves for clonidine and dexmedetomidine are shown by a broken line. The ED$_{50}$ and 95% confidence intervals are also shown.

gastric emptying was 2.3 for morphine but (by extrapolation) 365 for clonidine and infinity for dexmedetomidine.

The range of the reported ED$_{50}$ for the antinociceptive effect of morphine (table 3) includes the present ED$_{50}$ for gastric emptying (2.8 mg kg$^{-1}$). For clonidine and dexmedetomidine, however, the ED$_{50}$ values for antinociceptive effect (table 3) are very much less than the present ones for gastric emptying (lower limit of 95% CI: 4.6 mg kg$^{-1}$ for clonidine and 4.3 mg kg$^{-1}$ for dexmedetomidine). Therefore, it is unlikely that clonidine and dexmedetomidine at antinociceptive doses strongly inhibit gastric emptying, whereas it is likely for morphine.

There are several differences between alpha$_2$ adrenoceptor agonists and opioids in the mechanisms of their effects on gastric motility. First, alpha$_2$ adrenoceptor agonists inhibit the contraction of the stomach caused by stimulation of cholinergic neurones,[28–30] but not that induced by exogenous acetylcholine,[28 29] and these agonists may not lower the basal tone of the stomach.[28 30] In contrast, opioids strongly inhibit both basal and stimulated gastric motility.[31 32]

*Table 3* The reported ED$_{50}$ (mg kg$^{-1}$) for the antinociceptive effect of clonidine, dexmedetomidine and morphine injected either i.p. or s.c. in rats (unless specified). [a]The 0.05 mg kg$^{-1}$ produced 70% inhibition. [b]This value was obtained in mice; no data were available for rats

| | Type of nociceptive stimuli | ED$_{50}$ (mg kg$^{-1}$) | References |
|---|---|---|---|
| Clonidine | Thermal | 0.1–2.7 | [18, 23, 24] |
| | Chemical | 0.08–0.15 | [18, 23] |
| Dexmedetomidine | Thermal | <0.05[a] | [25] |
| | Chemical | 0.01[b] | [14] |
| Morphine | Thermal | 0.6–8 | [23, 26, 27] |
| | Chemical | 0.4–0.8 | [23, 26] |

Second, opioids increase pyloric pressure[33 34] leading to delay in gastric emptying. In contrast, alpha$_2$ adrenoceptor agonists either have no effect or relax the pylorus[35–37] and thus the pylorus does not impede emptying of gastric contents. However, a dilated pylorus may increase duodenogastric reflux,[37] and if so, net gastric emptying may be delayed. This may explain why there was a mild delay in gastric emptying after injection of clonidine and of dexmedetomidine in our study.

### POSSIBLE REASONS FOR DISCREPANCIES BETWEEN STUDIES

There have been two reports in which the effects of clonidine on gastric emptying of liquids were studied in the rat. Cooper and McRitchie found that clonidine 0.003–1.0 mg kg$^{-1}$ strongly inhibited gastric emptying of 5 ml of test liquid.[9] In contrast, Ruwart, Klepper and Rush found that clonidine up to 1.0 mg kg$^{-1}$ did not inhibit gastric emptying of 0.25 ml of test liquid, but strongly inhibited small intestinal transit.[6] The results of the Ruwart, Klepper and Rush study are similar to ours for clonidine using 1.0 ml of test liquid.

The reasons for the discrepancies between studies are not clear, but one possible cause is the difference in the volume of test liquids used. Because clonidine strongly inhibits intestinal transit, it is likely that the greater the volume of a test liquid infused into the stomach, the greater the pooling of the liquid in the duodenum. Distending the duodenum stimulates reflex relaxation of the stomach.[38–40] In the rat, distension of the duodenum by direct infusion with as little as 0.05 ml of saline relaxes the stomach, and the degree of gastric relaxation depends on the degree of distension of the duodenum.[38] Gastric emptying is delayed when the stomach is relaxed, because emptying is influenced by a pressure gradient between the stomach and the duodenum.[39] Cooper and McRitchie[9] infused a large volume of liquid (5 ml) into the stomach, whereas Ruwart, Klepper and

Rush[6] used a much smaller volume (0.25 ml); therefore, it is likely that the degree of distension of the duodenum and thus the degree of relaxation of the stomach would have been the greatest in the Cooper and McRitchie study[9] and least in the Ruwart, Klepper and Rush study.[6] Therefore, this may explain the marked delay in gastric emptying found in the study of Cooper and McRitchie[9] and the absence of delay in the Ruwart, Klepper and Rush study.[6]

The marked inhibition of gastric emptying in the study of Cooper and McRitchie[9], however, may not be physiological. We found that, when 5 ml of liquid were infused into isolated rat stomachs, there was marked distension and thinning of the gastric wall (unpublished observation). Thus the stomach was likely to be over distended in their study. In addition, increase in gastric volume relaxes the gastric tone[40 41] by stimulating the non-adrenergic, non-cholinergic vagal nerve.[42] These differences in the conditions of the stomach may also contribute to an explanation of the discrepancy.

### POSSIBLE CONFOUNDING FACTORS

We gave halothane to rats to insert an orogastric cannula. This might have affected the data. However, it is unlikely that halothane caused the difference in the transit between groups in our study, because halothane was used in both control and test groups, and also because the effect of clonidine and morphine was antagonized by yohimbine and naloxone, respectively.

It is also not clear if the inhibitory effect of clonidine and dexmedetomidine on gastric emptying and gastrointestinal transit is a direct effect or a secondary effect derived from other factors, such as decreased arterial pressure, heart rate or body temperature.

### GASTRIC EMPTYING AND GASTROINTESTINAL TRANSIT

In this study, clonidine and dexmedetomidine strongly inhibited transit in the small intestine, but only weakly inhibited gastric emptying. In contrast, atropine does not affect transit of liquids in the small intestine at doses that delay gastric emptying.[43] Caerulein, a cholecystokinin-like peptide, enhances intestinal transit but it either has no effect or even delays gastric emptying.[44] Furthermore, acoustic stress to mice accelerates gastric emptying without affecting gastrointestinal transit.[45] Thus it is likely that some of the mechanisms influencing gastric emptying are different from those influencing transit in the intestine.

### CLINICAL IMPLICATIONS

There are similarities between humans and rats in terms of the presence of opioid and $\text{alpha}_2$ adrenoceptor receptors in the gastrointestinal tract and in terms of behavioural effects (such as the antinociceptive effect) of opioids and $\text{alpha}_2$ agonists. Therefore, although the present $ED_{50}$ values cannot be transferred to humans, it is likely that, at antinociceptive doses, clonidine and dexmedetomidine would produce less inhibition of gastric emptying (relative to that on gastrointestinal transit) than does morphine.

In summary, we have shown that, in the rat, morphine inhibited both gastric emptying and gastrointestinal transit via opioid receptors to a similar degree, whereas clonidine and dexmedetomidine did so via $\text{alpha}_2$ adrenoceptors with only a weak inhibitory effect on gastric emptying, even at the maximum tolerable dose.

## Appendix

The method provided by the GLIM package, of fitting a sigmoid logit curve directly to the fractional inhibition, is usually used when each datum is in the form of *r* responders of a total of *n* subjects. The procedure assumes that the residuals conform to the binomial distribution in which the variance is a function of the fitted value of the proportion of individuals responding (*r/n*). Applying the process to fitting fractional inhibition in each rat resulted in residuals approximately 10 times greater on average than those of the binomial distribution; but this was compensated by using a scaling factor to correct for "over dispersion" as explained in the GLIM manual.[19] This implies the assumption that the variance of the residuals depended on the fitted proportion in the same way as in the binomial distribution—apart from the scaling factor. In other words, that the residuals were distributed in a manner proportional to the binomial distribution.

To test this assumption, the variance of the observed values from the fitted value was calculated for each dose of each agent, for both gastric emptying and gastrointestinal transit, including data from studies of two other agents, nalbuphine and pentazocine. This provided a total of 64 variances. The ratios of these variances to the corresponding binomial variances ranged from approximately 0.4 to 1 3 times the mean ratio—a range of approximately 3:1.

The data were also analysed using the conventional method of fitting a straight line to the logit of the fractional inhibition and assuming that the residuals were normally distributed. This implies that the variances were the same for all levels of inhibition; in fact they varied from 0.15 to 1.5 times the mean variance—a range of approximately 10:1.

Therefore, although the assumptions of the method we used were not entirely met, they were considerably more closely met, for our data set, than the assumptions involved in the conventional approach. It is also important to note that the $ED_{50}$ values from the conventional approach were all well within the 95% confidence limits of those obtained by the adopted method.

## Acknowledgement

We thank Mr C. Juniper, HNC, for his skilful technical assistance, Dr W. D. Evans, Department of Medical Physics and Bioengineering, for his advice and help in the use of the gamma counter, and Mrs P. de Souza, Department of Haematology, for providing the radiolabelled liquid. We also thank Orion-Famos Pharmaceuticals, Turku, Finland, for the generous gift of dexmedetomidine.

SHORT COMMUNICATIONS

# Detection of inspiratory resistive loads after anaesthesia for minor surgery

G. B. DRUMMOND AND J. P. CULLEN

## Summary

We measured the ability to detect inspiratory resistances in 22 patients undergoing minor gynaecological surgery, using linear resistances of 1.2–24.4 cm $H_2O$ litre$^{-1}$ s, and ranked 1–9. The rank that could be detected was measured before surgery, approximately 10 min after recovery from anaesthesia, and then 25 min later. After anaesthesia there was a significant increase ($P<0.001$) in the rank number by 2, which returned to preoperative values 25 min later. Minute ventilation was reduced by 25% after operation and this may partly explain this change; however, we believe the transient decrease in ability to sense resistance indicates residual effects of anaesthetics and may explain in part the incidence of hypoxia caused by airway obstruction in patients after anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 308–310).

**Key words**
Complications, airway obstruction. Hypoxaemia. Lung, respiratory resistance.

Episodes of hypoxaemia are common immediately after operation and are also frequent later, in association with treatment with opioids, where airway obstruction appears to be the cause.[1] Anaesthetic agents and opioids are known to reduce responses to hypoxia and hypercapnia but they may perhaps also reduce responses to other effects of airway obstruction. Such responses may be protective. For example, some patients with severe asthma have a reduced capacity to detect inspiratory resistance and have reduced responses to hypoxia. Such patients are more likely to suffer severe consequences in association with attacks of asthma, such as loss of consciousness or mechanical ventilation.[2] To assess the possibility that other responses to airway obstruction could be affected after anaesthesia, we tested the ability of patients to detect a threshold inspiratory resistive load before, immediately after and later after minor surgery with general anaesthesia.

## Methods and results

After obtaining local Ethics Committee approval and informed written consent, we recruited women undergoing minor gynaecological surgery as day-case patients. We noted any current medication, smoking history, a history of airway disease or exposure to pollutants, and also noted if the patient appeared unduly anxious.

We used a series of resistances constructed using different numbers of glass capillary tubes (6 cm long, of the type used for measuring erythrocycte sedimentation rate) mounted in parallel in a supporting tube. They were linear within 5% for flow rates of up to 30 litre min$^{-1}$ and had resistances of 1.2, 1.7, 2.5, 2.8, 3.8, 8.3, 10.3, 11.5 and 24.4 cm $H_2O$ litre$^{-1}$ s. Calibration was performed with a laboratory manometer system (for the purposes of statistical analysis, however, they were numbered 1–9 and considered as ranked values on an ordinal rather than an interval scale). Each resistance could be fitted in turn to a respiratory system.

The patient lay recumbent and wore a noseclip, and breathed from a mouthpiece connected to a unidirectional low resistance anaesthetic valve (Ambu Hesse). Valve resistance was 2 cm $H_2O$ litre$^{-1}$ s at an inspiratory flow rate of 3 litre s$^{-1}$. The inspiratory side of the valve was connected to a large bore three-way tap by means of a wide bore tube, 70 cm in length, so that a resistance could be added for a single inspiratory effort, unknown to the subject. She was asked to indicate by hand movement if she felt a change in the effort of breathing. The resistances were added each in turn until the patient reliably indicated it had been felt. The patient also breathed from the mouthpiece while minute volume and frequency were measured over 1 min with an electrical Wright respirometer (Ferrari) connected to the expiratory limb of the circuit. This device had been calibrated recently by the manufacturer.

The anaesthetic induction agent was restricted to propofol, but anaesthesia and surgery were not otherwise standardized. During and after surgery analgesics were given as judged necessary and all agents used were noted, including a plot of end-tidal concentration of the volatile agent *vs* time.

The minimum resistance detected, and minute volume and ventilatory frequency, were measured again immediately after recovery from anaesthesia, soon after the patient could co-operate with the test,

---

and also after the patient had fully recovered and had returned to the ward. If the patient could not detect a resistance after recovery from anaesthesia, this response was scored as 10.

Data were analysed with the sign test and sign confidence limits to compare changes within patients with time, the Mann–Whitney test to compare subgroups, and descriptive plots using Minitab release 8 run in MS-DOS 6.2.

We recruited 25 patients but three did not complete the study. Of the remaining 22, one patient did not have measurements made in the ward. Mean age was 30 yr, height 160 (SD 7) cm and weight 62 (14) kg. Four patients reported mild asthma but none was currently receiving treatment. Nine were smokers and two were exposed to dust. Before anaesthesia minute volume was 8.7 (7.4–9.6) litre $\text{min}^{-1}$ and ventilatory frequency was 17 (13–19) bpm (median, quartiles). After recovery from anaesthesia the corresponding values were 6.3 (4.9–7.7) litre $\text{min}^{-1}$ and 15 (13–17) bpm, and on testing in the ward these values were 8.3 (6.4–9.2) litre $\text{min}^{-1}$ and 15 (14–17) bpm. Changes in ventilation were statistically significant ($P<0.001$ and 0.05, respectively), but changes in frequency were not.

The propofol dose used was 200 (165–300) mg, and duration of anaesthesia and surgery was 17.5 (10–21.5) min. The responses to loads were measured 11 (10–13) min after the end of anaesthesia. The tests in the ward were performed at 36 (30–42) min after the end of anaesthesia. Surgical procedures ranged from examination under anaesthesia to laparoscopic procedures. The anaesthetic techniques included intubation of the trachea, administration of neuromuscular blocking agents and morphine analgesia. However, the maximum duration of anaesthesia was only 25 min. Three patients received desflurane and the remainder enflurane, all in nitrous oxide, and the expired volatile agent concentrations were almost equipotent with no large variations in the concentrations administered. Seven patients received either fentanyl or alfentanil in small amounts and seven received morphine during operation.

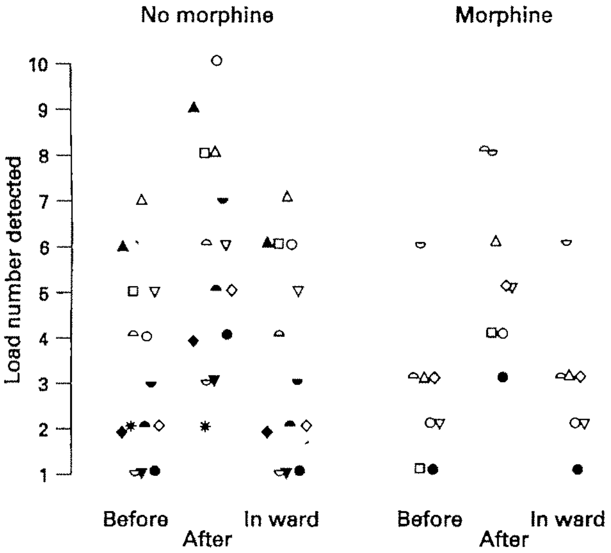

*Figure 1* Rank load number detected by each patient. Values are for before anaesthesia, immediately afterwards and after return to the ward. Patients who received morphine during surgery are shown separately and within each category each patient is represented by a different symbol.

The resistances detected are shown in figure 1. In each circumstance, patients were consistently able to identify a single load. Before operation the rank of resistance was median 2.5 (95% confidence intervals 2–4) and this increased to 5 (4–7) after operation and decreased to 3 (2–4) after return to the ward. The increase in resistance for detection after operation was significant ($P<0.001$) and there was no difference between the rank values before operation and after return to the ward.

There was no relationship between changes in minute volume and ventilatory frequency in individual patients, and the changes in detection of the load. The loads detected by patients who had received morphine in the intraoperative period (seven patients, median dose 15 (8–15) mg) were only greater by one rank, and 95% confidence limits for change in rank were almost identical. Two patients received topical anaesthesia to the trachea before intubation using lignocaine. They did not show excessive changes in load detection, the load detected increasing by two rank values in each case. No other factors associated with anaesthesia and surgery appeared to affect the resistance threshold. In particular, duration of surgery and time between i.v. induction agent and testing were not related to change in the rank of resistance detected.

## Comment

Appreciation of resistive loads is altered by changes in inspiratory flow rate.[3] After operation, mean inspiratory flow rate is likely to have been reduced by approximately 25% as expired minute volume was reduced by a median of 2.1 litre $\text{min}^{-1}$ from 8.6 litre $\text{min}^{-1}$, with no significant change in ventilatory frequency. This may have reduced the sensation of the resistance slightly but it is unlikely that this factor alone was responsible for the increase in load rank of 2.5. In addition, ventilation increased by only 1.1 litre $\text{min}^{-1}$ in the ward 30 min later and at this time load detection had returned to values found before operation. The resistive loads we used were not great: the greatest load in the series causes moderate dyspnoea in normal subjects (on a standardized linear verbal rank scale). Detection of a resistive load seems to be proportional to the proportional increase in resistance it generates (the Weber law)[3] and thus comparison of loads between subjects is of less value than changes in perception within subjects.

We measured the conscious appreciation of the load by the patient. This response may not reflect the response of the respiratory muscles to increased inspiratory resistance: there may continue to be an increase in muscle activation or force generation in response to the load, but conscious appreciation of the presence of the load is impaired.

The anaesthetic and surgical procedures that we studied were not standardized other than in the use of a single, relatively short-acting induction agent. In many respects the patients were heterogeneous, in terms of anxiety, postoperative pain and management (use of different opioids with various durations of action, and airway management by face mask, laryngeal mask or tracheal intubation). Further study of more uniform groups may allow factors responsible for the changes to be more established clearly, but this study did show a clear effect in a common clinical setting. The time course of the resolution of the effect suggests that the cause was residual anaesthetic agents. If this were the induction agent, the effect would be greater in patients who had short procedures: if it were the volatile agent then the effect would be more marked after the longer procedures. No such effects were evident.

Factors that protect patients from hypoventilation and resultant hypoxia, apart from vigilance of their attendants and oxygen therapy, are not well understood. The awake subject breathes with more force when inspiration is impeded but the influence of residual anaesthetic agents or opioids on detection and response to this response is not clear. Despite experimental evidence for responses to airway pressure, mediated by sensory information from the airways,[4] these responses seem to be inactive in sleeping humans. In sleeping subjects, airway obstruction causes increases in tongue muscle activity only after a complete respiratory cycle of obstruction. Then, airway muscle activity increases in parallel with activity in other respiratory muscles such as the diaphragm.[5] In fact, detection of airway resistance appears to be mediated by changes in intrapulmonary pressure.[6]

We conclude that after short periods of anaesthesia with relatively short-acting agents such as propofol, enflurane, and isoflurane, patients responded less well to minor transient airway obstruction, even when awake. The use of moderate amounts of opioids (morphine) did not appear to affect impairment, although we did not formally investigate this factor and patients who received morphine may have been systematically different from those who did not.

# Does intrathecal fentanyl produce acute cross-tolerance to i.v. morphine?

D. W. COOPER, S. L. LINDSAY, D. M. RYALL, M. S. KOKRI, S. S. ELDABE AND G. A. LEAR

## Summary

We have examined the hypothesis that intrathecal fentanyl at operation can increase postoperative i.v. morphine requirements. We studied 60 patients undergoing Caesarean section. All received intrathecal 0.5% plain bupivacaine 2 ml combined with either fentanyl 0.5 ml (25 μg) (group F) (*n*=30) or normal saline 0.5 ml (group S) (*n*=30). In addition, 10 ml of an extradural solution (fentanyl 1 ml (50 μg) combined with 0.5% bupivacaine 9 ml ) was administered after delivery. Extradural solution was only given before delivery if the intrathecal injection failed to produce a block above T6 or the patient required further analgesia. Postoperative analgesia was provided with i.v. morphine patient-controlled analgesia. At operation, intrathecal fentanyl reduced the need to administer extradural solution before delivery, increased the anaesthetist's satisfaction with analgesia and reduced nausea, but increased pruritus. Up to 6 h after delivery there was no difference in postoperative morphine requirements or pain scores. Between 6 h and 23 h there was a 63% increase in morphine requirements in group F. We consider the most likely explanation for this finding to be that intrathecal fentanyl induced acute spinal opioid tolerance. (*British Journal of Anaesthesia* 1997; **78**: 311–313).

**Key words**
Anaesthetic techniques, extradural. Anaesthetic techniques, intrathecal. Anaesthesia, obstetric. Anaesthetics local, bupivacaine. Analgesics opioid, fentanyl. Analgesics opioid, morphine. Pain, postoperative. Potency, analgesic. Potency, drug, tolerance.

A prospective audit of postoperative i.v. patient-controlled analgesia (PCA) at our institute produced an unexpected observation. During the first 24 h after regional anaesthesia for Caesarean section, the dose of morphine was 47% greater for patients who had received intrathecal fentanyl at operation compared with those who had not. This led us to hypothesize that intrathecal fentanyl at operation can increase postoperative i.v. morphine requirements. In order to examine this hypothesis we have conducted a controlled study.

## Methods and results

This randomized, double-blind study was approved by the local hospital Ethics Committee. After obtaining informed consent we studied 60 ASA I–II patients undergoing morning elective Caesarean section.

Combined intrathecal and extradural analgesia was performed at L3–4 or an adjacent space. Patients received 0.5% plain bupivacaine 2 ml intrathecally combined with either fentanyl 0.5 ml (25 μg) (group F) (*n*=30) or normal saline 0.5 ml (group S) (*n*=30). The intrathecal solution was prepared by an anaesthetist who was not involved with patient management.

The extradural solution (10 ml) was prepared by combining fentanyl 1 ml (50 μg) with 0.5% bupivacaine 9 ml. This was administered between delivery and the end of operation when block regression would allow. Increments were only given before delivery if the intrathecal injection failed to produce a block above T6 or the patient required further analgesia. Additional extradural solution, consisting of 0.5% bupivacaine without fentanyl, could also be administered to achieve adequate block. If additional analgesia was needed after delivery then i.v. alfentanil was given as required. At the end of operation patients received rectal diclofenac 100 mg, unless contra-indicated. I.v. morphine was available via a disposable PCA device. This delivered a maximum bolus of 1 mg with a 5-min chamber refilling time. No more diclofenac was given before completion of the study at 10:00 on the first morning after operation.

At the end of operation the volume and timing of extradural solution given were recorded. The most severe pain experienced during operation was assessed using a visual analogue score for pain (VAS) (100-mm scale: 0=no pain, 100 mm=worst pain imaginable). The presence or absence of nausea, vomiting, pruritus and drowsiness during operation was assessed by the patient. Pruritus and drowsiness were graded as mild, moderate or severe. Both the anaesthetist and the patient made a verbal rating score (VRS) for satisfaction with analgesia during operation (0=excellent, 1=good, 2=fair, 3=poor).

The amount of morphine self-administered was

| Groups F/S | | | | | |
| During operation | 27/57 † | 7/20 | 60/7† | 43/20 $P=0.06$ | |
| In recovery (REC) | 7/3 | 0/0 | 63/13† | 40/20 $P=0.09$ | |
| REC–3 h | 10/7 | 3/4 | 63/41† | 47/26 | |
| 3–6 h | 17/14 | 7/0 | 30/34 | 62/59 | |
| 6–10 h | 34/41 | 14/21 | 38/43 | 79/56 | |
| 10–23 h | 35/27 | 14/12 | 69/65 | 83/59 | |

recorded at 3, 6 and 10 h after delivery and at 10:00 on the first morning after operation. VAS at rest and on coughing was recorded in recovery at 15 min after operation (REC), at 3, 6 and 10 h after delivery and at 10:00. Assessments of side effects were made in recovery and for the periods REC–3 h, 3–6 h, 6–10 h and 10 h–10:00. A VRS for satisfaction with postoperative analgesia was recorded at the end of the study.

A computer package (SPSS) was used for statistical analysis. Results were compared using Mann–Whitney and Kruskal–Wallis tests, with $P<0.05$ taken as significant.

Two groups of 30 patients were studied. They were matched for age, height, weight, previous Caesarean section, duration of operation, tubal surgery and duration of study. Group F received a similar total dose of extradural solution (median 10 (interquartile range (IQR) 10–10) ml) as group S (10 (IQR 10–10) ml). However, before delivery, less extradural solution was given in group F; 17% of group F received extradural supplementation (5 (IQR 3–11) ml) compared with 40% of group S (9 (IQR 5–10) ml) ($P<0.05$, Mann–Whitney). I.v. alfentanil was given to 7% of patients in group F compared with 23% in group S ($P=0.07$, Kruskal–Wallis). Median pain scores for the most severe pain experienced during operation were 0 (IQR 0–13) mm for group F and 6 (IQR 0–18) mm for group S ($P=0.07$, Mann–Whitney). The anaesthetist's satisfaction with operative analgesia was greater for group F (93% excellent, 3% good, 3% fair, 0% poor) than for group S (72% excellent, 17% good, 10% fair, 0% poor) ($P<0.05$, Kruskal–Wallis), but there was no difference in patient satisfaction with analgesia. Intrathecal fentanyl reduced nausea during operation but increased pruritus: 60% of group F were itchy (44% mild, 44% moderate and 11% severe) compared with 7% of group S (100% mild) (table 1).

Two patients in group F and one patient in group S did not receive diclofenac. Patients were studied for a mean of 23 h after delivery (table 1). Up to 6 h after delivery there was no difference in morphine requirements. Between 6 and 23 h after delivery morphine requirements were 63% greater for group F. There was no difference in postoperative pain scores, patient satisfaction with analgesia, nausea, vomiting or drowsiness. The increased pruritus with intrathecal fentanyl persisted into the early postoperative period.

## Comment

These results support the hypothesis that intrathecal fentanyl at operation can increase postoperative i.v. morphine requirements.

How could this be explained? If there was greater pre-emptive analgesia with intrathecal fentanyl it would have been expected to produce the opposite effect to that encountered. The most likely explanation is that intrathecal fentanyl produced acute opioid tolerance. Acute tolerance at the spinal level could increase systemic morphine requirements in two ways; first, by reducing the effect of morphine acting directly on spinal receptors; second, indirectly, by reducing the effect of endogenous spinal opioids. This could also reduce the effectiveness of supraspinal morphine acting via the descending pain control pathways.

Tolerance is a well recognized phenomenon that is dependent on dose of opioid and duration of exposure. With i.v. fentanyl acute tolerance can develop in dogs within 3 h.[1] Spinal opioids can also produce tolerance but it has not been considered to be a problem with short-term postoperative extradural or intrathecal use.[2]

High lipophilicity limits rostral spread after intrathecal administration. This can allow high concentrations of opioid at the spinal level without producing clinically significant respiratory depression or sedation. We believe that high spinal receptor occupancy with the potent opioid fentanyl produced acute tolerance after a single intrathecal dose. Nociceptive stimulation has been reported to inhibit the development of tolerance.[3] Local anaesthetic block and rectal diclofenac may therefore have contributed to the development of acute tolerance by reducing nociception. The use of extradural fentanyl may also have contributed to its development by increasing the total spinal dose.

Intrathecal fentanyl was beneficial at operation, reducing extradural anaesthetic requirements and increasing the anaesthetist's satisfaction with operative analgesia. Nausea was also reduced, probably because of more effective visceral afferent inhibition, but pruritus increased. After operation we found no benefits from intrathecal fentanyl. The lack of a difference in postoperative analgesia within the first 6 h was probably because both groups received extradural analgesia and rectal diclofenac.

We consider that this study provides evidence for a single dose of intrathecal fentanyl producing acute spinal opioid tolerance. This phenomenon clearly warrants further investigation. Our findings, in conjunction with a previous study which found no advantage from using more than 6.25 μg of intrathecal fentanyl,[4] have led us to reduce the total dose of spinal fentanyl given to Caesarean section patients.

# Mechanism of femoral nerve palsy complicating percutaneous ilioinguinal field block

D. J. ROSARIO, S. JACOB, J. LUNTLEY, P. P. SKINNER AND A. T. RAFTERY

## Summary

Femoral nerve palsy has been reported after percutaneous ilioinguinal field infiltration with general anaesthesia for inguinal herniorrhaphy. The mechanism whereby this could occur was studied in cadaver dissections. It was found that the plane between the transversus abdominis muscle and the transversalis fascia was continuous laterally with the tissue plane deep to the iliacus fascia, which is the plane containing the femoral nerve. Injection of methylene blue 1 ml into this plane resulted in pooling of dye around the femoral nerve. Femoral nerve palsy may result from infiltration of a sufficient volume of local anaesthetic into the plane between the transversus abdominis muscle and the transversalis fascia with tracking of the injectate deep to the iliacus fascia to affect the femoral nerve. This finding has important implications for the performance of a percutaneous ilioinguinal field block particularly in day surgery provision. (*Br. J. Anaesth.* 1997; **78**: 314–316).

**Key words**
Anaesthetic techniques, regional, inguinal. Complications, nerve palsy.

Transient femoral nerve palsy (FNP) has been reported after percutaneous ilioinguinal field block (PIIFB) for inguinal herniorrhaphy.[1 2] In all cases discharge from hospital was delayed and serious injury was sustained by one patient.[2] The femoral nerve lies on the posterior abdominal wall covered by the strong iliacus fascia[3] and it is unlikely that simple diffusion of the local anaesthetic agent through tissue layers could result in FNP. Sufficient local anaesthetic to cause block must enter the plane deep to the iliacus fascia and there are potentially two routes whereby this may occur: (i) local anaesthetic is infiltrated directly under the iliacus fascia around the femoral nerve; (ii) local anaesthetic tracks around tissue planes to enter this plane and involve the femoral nerve.

This cadaver study was carried out in an attempt to elucidate the most likely mechanism whereby this complication could occur.

## Methods and results

We examined 21 cadavers with the abdominal contents removed in this anatomical study. In all cases the posterior and anterolateral abdominal walls had been left untouched and the parietal layers were exposed medially. A standard approach[4] to a PIIFB was used with a 22-gauge short bevel spinal anaesthetic needle inserted vertically through the skin at a point 3 cm medial to the anterior superior iliac spine (ASIS). The muscle and fascial layers traversed by the needle were observed and their thickness measured. The distance in the transverse axis between the femoral nerve and the point at which the vertically inserted needle made contact with the posterior abdominal wall was also measured. In three cases, sequential injections of methylene blue 1 ml were carried out first into the plane superficial to the transversus abdominis muscle and subsequently into the plane between that muscle and the transversalis fascia to examine the direction and extent of spread.

### ABDOMINAL WALL

The layers traversed in passing the needle from the anterior to the posterior abdominal wall are skin, subcutaneous fat, external oblique aponeurosis, internal oblique and transversus abdominis muscles, transversalis fascia, extraperitoneal fat, iliacus fascia and finally the iliacus muscle itself. In all cases the combined thickness of the internal oblique and transversus abdominis was less than 5 mm.

### DISTANCE FROM THE FEMORAL NERVE

Mean distance from the needle point to the femoral nerve along the posterior abdominal wall was 4.5 (95% confidence interval 0.3) cm in female cadavers ($n=11$) and 3.2 (0.3) cm in males ($n=9$). This difference between the sexes was highly significant ($P<0.0001$ Student's $t$-test).

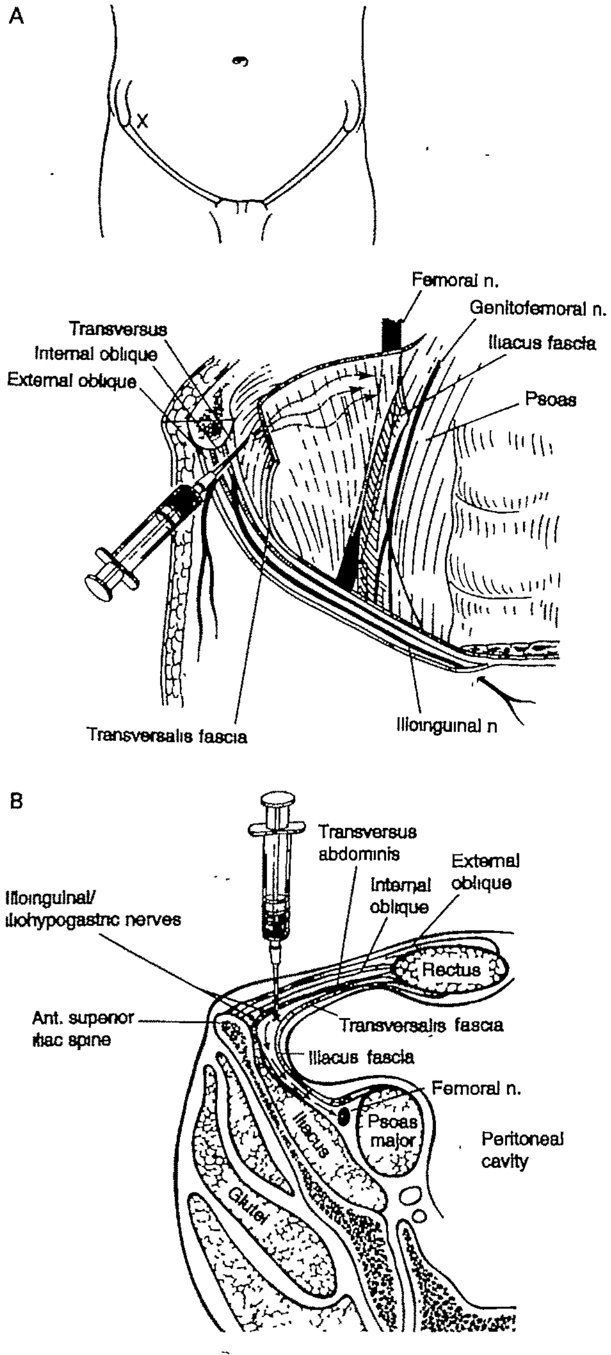

*Figure 1* A: Three-dimensional schematic representation of the body layers at the level of the anterior superior iliac spine and observed direction of spread of injectate after injection deep to the transversus abdominis muscle. B: Cross-sectional diagram of the pelvis at the level of the ASIS demonstrating reflection of the transversalis fascia as the iliacus fascia and the femoral nerve lying in the natural gutter lateral to the psoas.

### METHYLENE BLUE INJECTION

Injection of methylene blue 1 ml in the plane superficial to the transversus abdominis resulted in little dispersion of the injectate with discolouration remaining confined to the plane between that muscle and internal oblique. The transversalis fascia in all cases was continuous with and reflected laterally as the iliacus fascia (fig. 1). Injection of methylene blue 1 ml in the plane deep to the transversus abdominis involved advancement of the needle tip approximately 2–3 mm. Dye was seen consistently in all cases tracking medially and slightly cephalad under the iliacus fascia. Elevation of the iliacus fascia showed the dye pooling around the main trunk of the femoral nerve and other branches of the lumbar plexus.

## Comment

PIIFB is often used before inguinal herniorrhaphy as an adjunct to general anaesthesia to allow lighter anaesthesia in the perioperative period and for relief of postoperative pain. The technique carries morbidity as there have been five reported cases of prolonged FNP, with one patient suffering serious injury from a subsequent fall.[2] The incidence of FNP complicating PIIFB is uncertain but given the increasing trend towards day surgery provision, the incidence and associated morbidity of this complication, that is delayed ambulation, seems likely to increase. The ilioinguinal and iliohypogastric nerves lie initially between the transversus abdominis and the internal oblique, piercing the internal oblique at a variable distance medial to the ASIS to lie between the external oblique aponeurosis and internal oblique.[3] As segmental nerves (L1) they have a cutaneous distribution and also supply the parietal peritoneum; thus blockade of these nerves provides good analgesia after inguinal herniorrhaphy. The femoral nerve arises from the anterior rami of the lumbar nerves L2, 3 and 4 in the lumbar plexus. It emerges under the iliacus fascia at the lateral border of the psoas major to lie in a natural gutter between that muscle and the iliacus (fig. 1). We have seen from our dissections that dye injected into the plane between the muscles of the abdominal trunk, that is the correct plane for infiltration, remains confined to that plane. However, when injected deep to the transversus abdominis the dye tracks towards the femoral nerve under the iliacus fascia which is continuous laterally with the transversalis fascia While this study has demonstrated an anatomical mechanism for spread of local anaesthetic solution if injected in a plane too deep, we can make no definitive comment on the volume of injectate or rate of injection required to result in FNP. It must be noted that spread in the cadaver was achieved using only 1 ml of dye. Even allowing for differences in tissue conditions *in vivo* it seems likely that should sufficient local anaesthetic enter this plane, in the supine position the bony and fascial attachments of the fascial plane inferolaterally (to the ASIS and inguinal ligament) would cause tracking medially and pooling around the femoral nerve with resultant FNP.

An alternative explanation for the observed FNP is that the local anaesthetic is instilled directly around the nerve. Whereas it is not possible to totally discount this mechanism, we have seen from this study that the needle would have to be directed approximately 3–4 cm more medially than is recommended and this would therefore be unlikely. Of interest is the finding of a difference in the distance from the site of injection to the femoral nerve between males and females. The clinical significance of this is that FNP after PIIFB may be less likely to occur in females than males.

Our findings suggest that in a PIIFB for inguinal hernia repair, care should be taken to avoid injecting local anaesthetic deep to the transversus abdominis. This could be achieved by infiltrating the superficial layers, that is the skin and external oblique aponeurosis percutaneously and infiltrating the deeper layers and the ilioinguinal nerve under direct vision after exposure by the surgical incision. Should an entirely percutaneous approach be used, it is essential that the patient is informed of the potential risks, that nursing staff are informed and appropriate precautions are taken to prevent injury resulting from subsequent lower limb weakness.

# Effects of the pregnant uterus on the extradural venous plexus in the supine and lateral positions, as determined by magnetic resonance imaging

Y. HIRABAYASHI, R. SHIMIZU, H. FUKUDA, K. SAITOH AND T. IGARASHI

## Summary

To clarify the effects of the pregnant uterus on the extradural venous plexus in the supine and lateral positions, we studied magnetic resonance (MR) images of the lumbar spine in three parturients. T2-weighted axial MR images were obtained with the parturient in the supine and lateral positions. On each slice level in the same subject, the MR images were compared with the control MR images obtained before pregnancy. When the parturient lay supine, the pregnant uterus compressed the inferior vena cava and almost totally obstructed it; the extradural venous plexus was engorged. On turning the parturient into the lateral position, the inferior vena cava was free from compression, and the engorged extradural venous plexus was found to shrink to the level of the non-pregnant state. (*Br. J. Anaesth.* 1997; **78**: 317–319)

**Key words**
Anatomy, extradural space. Anaesthesia, obstetric. Measurement techniques, magnetic resonance imaging. Position, supine. Position, lateral. Position, effects.

Obstruction of the inferior vena cava by the pregnant uterus in the supine position diverts a proportion of the return of venous blood from the legs and pelvic structures into the vertebral venous system, causing the extradural venous plexus to engorge.[1] The lateral positioning of the gravida, however, is expected to resolve the vena caval obstruction.[2] Indeed, inferior vena cavogram of the parturient has shown that the lateral position decreases the inferior vena caval obstruction.[1] However, it is not clear if the pregnant uterus in the lateral position affects the extradural venous plexus. Our aim was to compare the lateral position with the supine position for the effects of the pregnant uterus on the extradural venous plexus using magnetic resonance (MR) imaging.

## Methods and results

The Institutional Review Board approved our study and informed consent was obtained. We studied three female volunteers, aged 29–30 yr. T2-weighted axial MR images of the second and third lumbar vertebrae were obtained using an MR imaging system (MRT-200/FXIII super version, Toshiba Corporation, Tokyo, Japan) operating at 1.5 T. Technical specifications included a repetition time of 3000 ms, an echo time of 112 ms, a slice thickness of 4 mm, number of slices 9 and a field of view of 15 cm. Control (non-pregnant) MR images were obtained before pregnancy with the subject in the supine position. At 32–34 weeks' gestation, MR images were obtained with the parturient in the supine position (pregnancy-supine) and the left lateral position (pregnancy-lateral). On each slice level in the same subject, we compared the three images (non-pregnant, pregnancy-supine and pregnancy-lateral). The area of the dural sac at the level of the intervertebral disc between the second and third lumbar vertebrae was measured using a digital planimeter (KP-90N, Uchida Yoko, Ltd, Tokyo, Japan).

Representative MR images are shown in figures 1–3 according to the levels of axial slice. With the parturient supine, the inferior vena cava was almost totally obstructed and the extradural venous plexus was engorged significantly (figs 1B, 2B, 3B). Both the medial and lateral components of the anterior internal vertebral veins were found to expand at the level of pedicles (fig. 1B); lateral components were noted to expand at the levels of the lamina and intervertebral disc (figs 2B, 3B). The engorged anterior internal vertebral veins displaced the anterior dural sac posteriorly (fig. 1B). When the parturient turned to the left lateral position, the inferior vena cava was free from compression and the engorged anterior internal vertebral veins were found to shrink in the lateral position (figs 1C, 2C, 3C). The areas of the dural sac at the level of the intervertebral disc between the second and third lumbar vertebrae (non-pregnant, pregnancy-supine and pregnancy lateral) were 2.0, 1.8 and 2.0 cm$^2$, respectively, in one subject, 1.5, 1.4 and 1.5 cm$^2$ in the second subject, and 1.8, 1.7 and 1.7 cm$^2$ in the third subject.

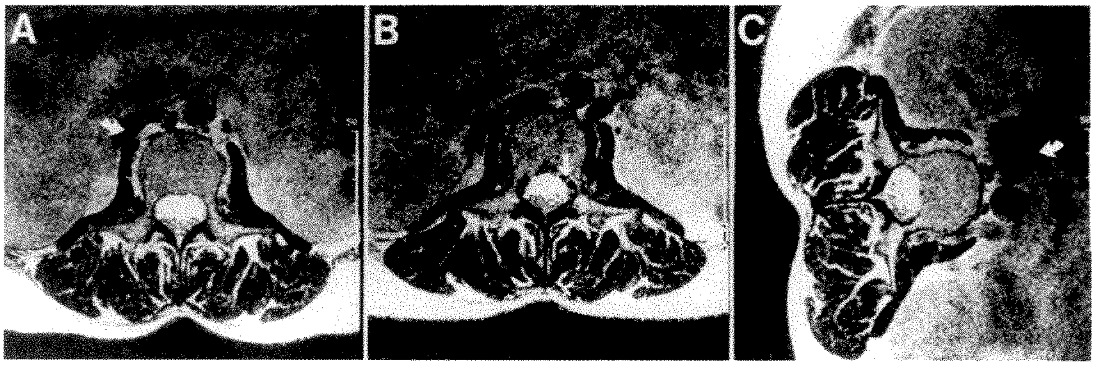

*Figure 1* T2-weighted MR image showing an axial section at the level of the pedicles of L2. A=Non-pregnant, B=pregnancy-supine, C=pregnancy-lateral. The inferior vena cava (curved arrow) was identified in the non-pregnant state (A) and in the pregnant-lateral position (C). Both the medial and lateral components of the anterior internal vertebral veins (vertical arrow) displaced the dura mater locally away from the walls of the vertebral canal (B). When the parturient turned to the left lateral position (C), the inferior vena cava was free from the compression and the engorged anterior internal vertebral veins shrank to the level of the non-pregnant state.

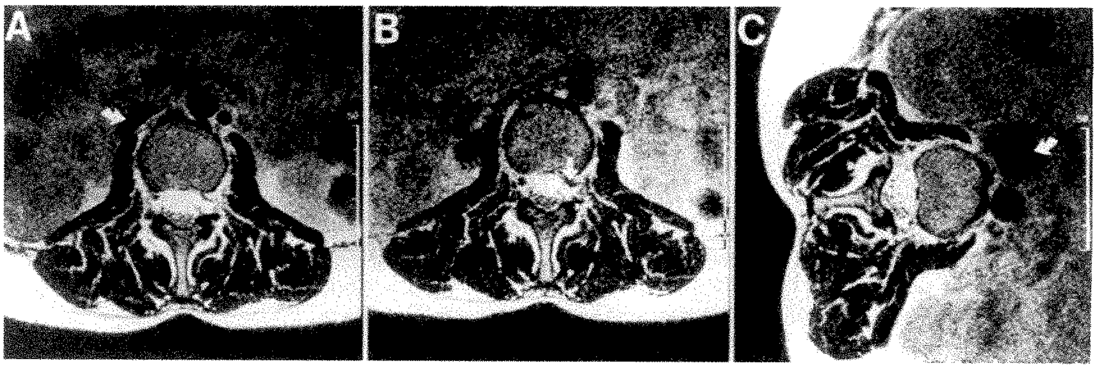

*Figure 2* T2-weighted MR image showing an axial section at the level of the lamina of L2 in the same subject. A=Non-pregnant, B=pregnancy-supine, C=pregnancy-lateral. The inferior vena cava (curved arrow) was identified in the non-pregnant state (A) and in the pregnant-lateral position (C). The lateral components of the anterior internal vertebral veins (vertical arrow) are noted to engorge in the supine position (B), whereas there is no engorgement of the extradural veins in the lateral position (C). The cauda equina was positioned at the posteromedial region of the dural sac in the supine position, while it migrated to the dependent side within the dural sac in the left lateral position.

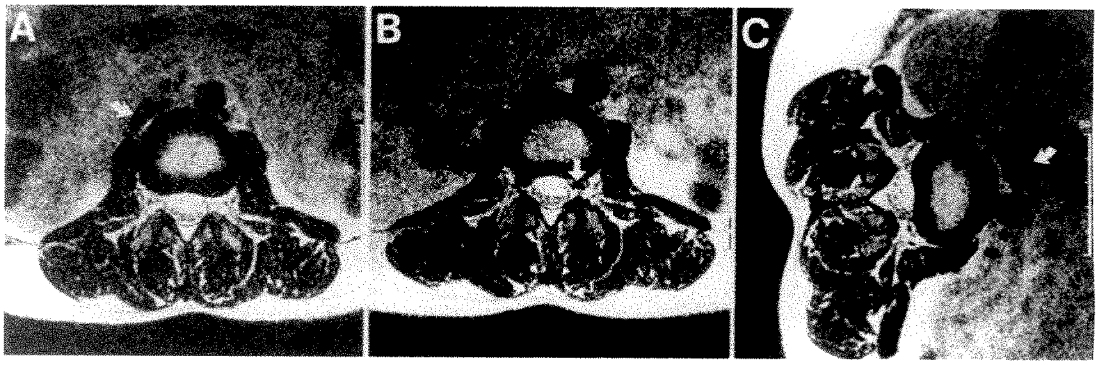

*Figure 3* T2-weighted MR image showing an axial section at the level of the L2–3 intervertebral disc in the same subject. A=Non-pregnant, B=pregnancy-supine, C=pregnancy-lateral. The inferior vena cava (curved arrow) was identified in the non-pregnant state (A) and in the pregnant-lateral position (C). The lateral components of the anterior internal vertebral veins (vertical arrow) are noted to engorge in the supine position (B), whereas there is no engorgement of the extradural veins in the lateral position (C). The fat-filled posterior extradural space remained unchanged at any time.

## Comment

The enlarged uterus in the later stages of pregnancy is expected to affect the return of venous blood from the legs and pelvic structures in two ways: first, the pregnant uterus may directly compress the inferior vena cava in the supine position, and second, it may increase intra-abdominal pressure globally. Of these, direct compression on the inferior vena cava may be resolved by lateral positioning of the gravida.[2] In this study, the inferior vena cava was found to be free from compression when the parturient turned to the left lateral position.

In contrast with direct compression on the inferior vena cava, a global increase in intra-abdominal pressure by the pregnant uterus may affect venous blood flow, regardless of the position. In non-pregnant women, the pressure in the inferior vena cava is normally 4–7 mm Hg in the supine position.[3] This pressure increases to 20–30 mm Hg in late pregnancy. On turning the parturient to the lateral position, the increased pressure was found to decrease rapidly to approximately 10–15 mm Hg.[4] This moderate pressure increase in the inferior vena cava in the lateral position may result from a global increase in intra-abdominal pressure by the enlarged pregnant uterus. In our parturients in the supine position, the anterior internal vertebral veins were found to engorge significantly. This engorgement of the anterior internal vertebral veins may result from diversion of the return of venous blood from the legs and pelvic structures to the vertebral venous system, which is induced by direct compression on the inferior vena cava in the supine position. On turning the parturient to the lateral position, the engorged anterior internal vertebral veins were found to shrink to the level of the non-pregnant state. This suggests that, with respect to the lateral position, the pregnant uterus may not divert the return of venous blood from the legs and pelvic structures to the vertebral venous system. It is unlikely that, in the lateral position, a global and moderate increase in intra-abdominal pressure associated with the pregnant uterus alone causes the extradural veins to engorge. The enlarged uterus during the later stages of pregnancy may cause the extradural venous plexus to engorge mostly by direct compression on the inferior vena cava rather than a global and moderate increase in intra-abdominal pressure.

Recently, Hogan and colleagues[5] investigated the effects of abdominal compression on CSF volume using MR imaging. The authors reported that abdominal compression decreased CSF volume, and that the mechanism by which increased abdominal pressure decreases CSF volume is probably inward movement of soft tissue in the intervertebral foramen, which displaces CSF. Unlike their study, we failed to demonstrate inward movement of soft tissue in the intervertebral foramen, while the engorged extradural venous plexus displaced the dural sac. Our findings are not directly comparable with theirs because both subjects and methods differed between the two studies. In addition, it is likely that the mechanism by which CSF volume is decreased in the parturient may differ from that in brief abdominal compression.

Although we showed that the inferior vena cava became free from compression and the engorged anterior internal vertebral veins shrank during the lateral position, the number of subjects studied was so small that the findings cannot be simply applied to the population as a whole. The availability of pre-pregnant controls, however, provided persuasive findings on the influence of the supine and lateral positions in determining extradural compliance and the volume of the dural sac at the level of the lumbar spine. It would be necessary to study a substantially larger population to confirm these findings and their relation to the spread of regional anaesthesia.

# Effect of lipid and propofol on oxidation of haemoglobin by reactive oxygen species†

N. STRATFORD AND P. MURPHY

## Summary

The clinical formulation of the i.v. anaesthetic propofol contains both the substrate for and inhibitor of lipid peroxidation. In these *in vitro* experiments we have investigated the importance of this potential conflict in a system where haemoglobin was oxidized by reactive oxygen species generated by hypoxanthine and xanthine oxidase. The presence of lipid in the system accelerated the rate of haemoglobin oxidation. Propofol inhibited lipid-induced acceleration but not the underlying rate of reactive oxygen species-induced oxidation. The rate of conjugated diene production, measured semi-quantitatively by ultraviolet absorption at 234 nm, was not reduced by propofol. Propofol may act by preventing haemoglobin oxidation by lipid hydroperoxides. (*Br. J. Anaesth.* 1997; **78**: 320–322)

**Key words**
Anaesthetics i.v., propofol. Blood, haemoglobin. Metabolism, lipids. Formulations, propofol.

Lipid peroxidation is a consequence of radical generation in biological tissues and may contribute to the tissue injury induced by oxidant stress. Propofol (2,6-diisopropylphenol) is an established inhibitor of radical-induced lipid peroxidation.[1 2] However, in its clinical formulation as Diprivan, this agent is dissolved in an emulsion of egg phosphatide, soya bean oil and glycerol, an emulsion vehicle similar to the i.v. feeding solution Intralipid. Diprivan therefore presents both substrate for and inhibitor of lipid peroxidation.

In these *in vitro* experiments we have considered the importance of this potential conflict by investigating the effect of propofol and lipid on a radical-mediated process—oxidation of ferrous haemoglobin by reactive oxygen species generated by a xanthine oxidase–hypoxanthine system. Haemoglobin is an attractive target as it is susceptible to easily measured oxidant-induced changes initiated by both reactive oxygen species and products of lipid peroxidation.[3] We speculated that lipid peroxidation might take place when reactive oxygen species (ROS) are generated in the presence of Diprivan or Intralipid. Therefore, in separate experiments, we followed the extent of this process by measuring the concentration of conjugated dienes, intermediate products of lipid peroxidation.

## Methods and results

Commercial human haemoglobin, largely methaemoglobin, was converted to the ferrous state by reduction with excess dithionite and purified by Sephadex gel separation. Solutions of oxyhaemoglobin 50 μmol litre$^{-1}$ in phosphate-buffered saline (pH 7.4) were incubated with a ROS generating system consisting of xanthine oxidase 0.01 u. ml$^{-1}$ and hypoxanthine 0.5 mmol litre$^{-1}$ at 37 °C for 4 h (all reagents from Sigma). Light absorbance at 560, 577 and 630 nm was measured spectrophotometrically (Pye Unicam PU 8600 UV/VIS) at the beginning of each experiment and after 2 and 4 h. The concentration of oxyhaemoglobin was calculated using equations derived from the known absorption coefficients of haemoglobin at each wavelength[3]:

$$[\text{oxyhaemoglobin}] = 0.0684A_{577} - 0.0014A_{560} - 0.0822A_{630}$$

where A=measured absorbance at each wavelength after correction for background absorbance measured at 700 nm. After 4 h, total haemoglobin concentration in our experiments decreased abruptly, making interpretation of oxidative changes impossible. The effect of including 0.005%, 0.01% and 0.02% Intralipid (Pharmacia) or propofol 25, 50 and 100 μmol litre$^{-1}$ as Diprivan (Zeneca) in the reaction flasks was examined. Concentrations of Intralipid provided an equivalent of the concentration of lipid accompanying each concentration of propofol formulated as Diprivan.

The amount of lipid peroxidation in the presence of either Intralipid or Diprivan was measured in a semi-quantitative manner by repeating the experiments in the absence of haemoglobin and measuring ultraviolet absorption at 234 nm. This provides a non-specific measure of conjugated dienes, a major product of polyunsaturated lipid peroxidation.

All experiments were performed six times and

†Presented in part at the Anaesthetic Research Society, Leeds Meeting, March 31–April 1, 1995 (*British Journal of Anaesthesia* 1995; 75: 229–230P).

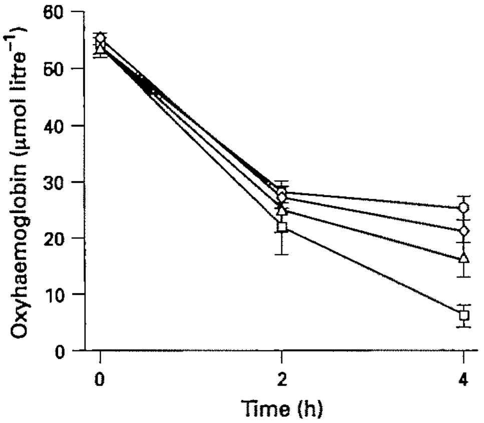

*Figure 1* Oxyhaemoglobin concentrations (mean, 95% confidence intervals) in experiments containing lipid. ○=Saline control, □=0.02% lipid, △=0.01% lipid, ◇=0.005% lipid.

results are expressed as mean (95% confidence intervals). Where there were differences, results were compared using two-way analysis of variance (ANOVA).

In the haemoglobin experiments there was a decrease in the concentration of oxyhaemoglobin over 4 h, consistent with ROS-mediated oxidation from the ferrous to the met-state. Haemoglobin oxidation was faster in flasks containing Intralipid than in saline control flasks (fig. 1). This effect was dependent on the concentration of lipid (two-way ANOVA, $P<0.001$). There was no difference in the rate of haemoglobin oxidation between Diprivan and saline control experiments.

In the haemoglobin-free experiments, absorbance at 234 nm increased steadily from 0 to 0.398 (95% confidence intervals 0.362–0.434) absorption units after 4 h in the Intralipid experiments and from 0 to 0.409 (0.373–0.445) absorption units over the same period in the Diprivan experiments. That there was no difference indicates that the formation of conjugated dienes occurred at the same rate in both Intralipid and Diprivan experiments.

## Comment

Xanthine oxidase catalyses the oxidation of hypoxanthine to xanthine with the consequent one electron reduction of molecular oxygen to the radical superoxide anion ($O_2^{\cdot-}$). Superoxide anions spontaneously dismute to produce hydrogen peroxide ($H_2O_2$). When exposed to this system, oxyhaemoglobin ($Hb\text{-}Fe^{2+}\text{-}O_2$) is oxidized to higher oxidation states such as met- ($Hb\text{-}Fe^{3+}$) and ferryl- ($Hb\text{-}Fe^{4+}$) haemoglobin.[4]

In these experiments we have shown that Intralipid potentiated the oxidation of oxyhaemoglobin by the xanthine oxidase–hypoxanthine system in a concentration-dependent manner. In contrast, the effect of propofol was more complex. It had no effect *per se* on oxidation of haemoglobin. However, because samples to which Diprivan was added did not exhibit the accelerated rates of oxidation observed in the Intralipid experiments, it is implied that propofol inhibited the effect of lipid. Thus propofol appeared to prevent lipid-induced acceleration of haemoglobin oxidation but did not reduce the underlying ROS-induced oxidation.

The mechanism underlying these observations is not clear. The increase in conjugated diene concentration during the course of the experiments is clear evidence of lipid peroxidation taking place when either Diprivan or Intralipid are exposed to this oxidant system. The process of lipid peroxidation is a self-propagating one which produces lipid hydroperoxides (LOOH) as end products. These species are themselves capable of oxidizing oxyhaemoglobin in a manner similar to the simplest hydroperoxide, hydrogen peroxide (HOOH). We hypothesize that the higher rate of haemoglobin oxidation observed in the presence of Intralipid is because of formation of lipid hydroperoxides.

The explanation for the activity of Diprivan is more complicated. Our experiments suggest that propofol within the formulation inhibits the effect of lipid on haemoglobin oxidation. There are several possible mechanisms for this. Propofol (P-OH) is a known inhibitor of lipid peroxidation.[1 2] It terminates the chain reaction of lipid peroxidation by reacting with lipid radicals forming a relatively stable phenoxyl radical ($PO^{\cdot}$).[5] However, failure of propofol to reduce the level of conjugated dienes formed during our experiments suggests that this is not the case in this system. Alternative explanations are that propofol either prevents the oxidation of haemoglobin by lipid hydroperoxides or that it reduces met-haemoglobin formed during the oxidative process back to the ferrous state. While there is evidence that the latter process can occur,[3] prevention of haemoglobin oxidation by lipid hydroperoxides is the most appealing explanation for our observations.

Failure to demonstrate a lower degree of lipid peroxidation in Diprivan compared with Intralipid experiments requires further comment. Other workers have shown that propofol at concentrations equivalent to or lower than those used here inhibit lipid peroxidation in liver microsome[1 6] and plasma models.[5] In some of these models the antioxidant activity of propofol was dependent on a supply of reduced glutathione, presumably to recycle the propofol phenoxyl radical species back to the reduced state.[2] No such system was available in our model. Furthermore, in our experiments the relative excess of lipid substrate may imply that any inhibitory effect on lipid peroxidation of the available propofol is simply swamped. Nevertheless, this is a relevant investigation as this is the formulation in which the drug is administered to patients for both anaesthesia and sedation in the intensive therapy unit.

The clinical implications of this study are not clear, but suggest that further investigation is required. The systemic inflammation exhibited by many critically ill patients in response to infection or trauma exposes them to an oxidant stress which is believed to contribute to subsequent tissue injury and secondary organ dysfunction. Further, lipid-containing solutions are often administered to this group of patients, either as part of a parenteral nutrition regimen or in the form of Diprivan to provide sedation. While it is not known if administration of lipid under such circumstances adds to a patient's oxidative stress, such a hypothesis would be worthy of examination. It is tempting to speculate that propofol could be a clinically useful antioxidant. However, both this work and that of Aarts and colleagues[2] have shown that, with regard to lipid peroxidation at least, simply giving a single antioxidant compound may not be the whole answer.

# Validation of thoracic electrical bioimpedance as a porcine research tool

C. J. BROOMHEAD, S. J. WRIGHT, K. M. KIFF AND P. S. WITHINGTON

## Summary

We have compared the accuracy of two methods of measuring cardiac output, thoracic electrical bioimpedance (TEB) and thermodilution (TD), in pigs. We studied four anaesthetized pigs, producing 145 paired cardiac output values over a range of TD cardiac outputs of 2.6–12.6 litre $\text{min}^{-1}$. TEB cardiac output was less than that measured by TD, by a constant factor throughout the observed range of values, because of differences in porcine thoracic shape. The Pearson product moment correlation coefficient suggested a good correlation ($r$=0.984, $P$<0.001). More importantly, analysis by the Bland and Altman statistical method suggested a high level of agreement, with 95% confidence intervals of ±1.0 litre $\text{min}^{-1}$. These results suggest that TEB can be used as a satisfactory method to measure cardiac output in porcine models. (*Br. J. Anaesth.* 1997; **78**: 323–325).

**Key words**
Measurement techniques, cardiac output. Measurement techniques, thoracic electrical bioimpedance. Measurement techniques, thermodilution. Pig.

Thermodilution is the most commonly used method of determining cardiac output. However, disadvantages associated with this technique, not least those caused by insertion of pulmonary artery catheters, are exaggerated in animal based research because of lack of familiarity with the anatomy. In contrast, thoracic electrical bioimpedance (TEB) is quick and simple to use, has minimal risks and provides continuous data. TEB has been used in humans, from neonates to adults, from the critically ill to the pregnant. Only one study has investigated its use in animals[1] and this can be criticized on the basis of statistical analysis as only a correlation coefficient was calculated. We have investigated the accuracy of TEB in a porcine model to assess its value as a research tool.

## Methods and results

We studied four unpremedicated large white pigs, weighing 40–50 kg. After induction of anaesthesia by inhalation of 5% halothane, and nitrous oxide in oxygen in a 50:50 mixture, the trachea was intubated and the lungs ventilated with a Cape-Waine ventilator and circle system. Anaesthesia was maintained with 2% halothane in a mixture of nitrous oxide in oxygen. Before surgery, continuous thoracic bioimpedance cardiac output monitoring was commenced (BoMed NCCOM3-R7 Continuous Cardiodynamic Monitor, Kimal Electronics Ltd, Cheshire, UK, using the software revision 7). Self-adhesive electrode pads, with two electrodes exactly 5 cm apart, were supplied by the manufacturers. Four pairs of electrodes are required, placed symmetrically on the thorax, at the base of the neck and in the midaxillary line at the level of the xiphoid process. An extra pair of electrodes placed over the cardiac apex ensures accurate monitoring of the ECG. Weight, height (snout to rump) and sex variables were entered, and cardiac output, averaged over 10 s, allowed stable data production.

Midline laparotomy allowed insertion of a Swan–Ganz catheter via the inferior vena cave and cannulation of the abdominal aorta. Cardiac output was measured by TD (Baxter EF1) using the mean of triplicate injections of 10 ml of iced 5% glucose injected as fast as possible at end-expiration. Repeated paired measurements of cardiac output by TD and TEB were performed every 10 min for 120 min. After this period, adrenaline infusions and progressive exsanguination were used to further extend the range of cardiac outputs over which measurements were obtained.

A total of 145 paired data points were collected over a range of TD cardiac output values from 1.7 to 8.6 litre $\text{min}^{-1}$. Differences in the shape of the porcine and human thorax generates a constant error in estimated cardiac output. Although TD cardiac output values were greater than TEB over the whole range of outputs measured, by multiplying TEB cardiac output values by a correction factor of 1.48, this error was eliminated.

The Pearson product moment correlation coefficient was $r$=0.984 with $P$<0.001. Data were also

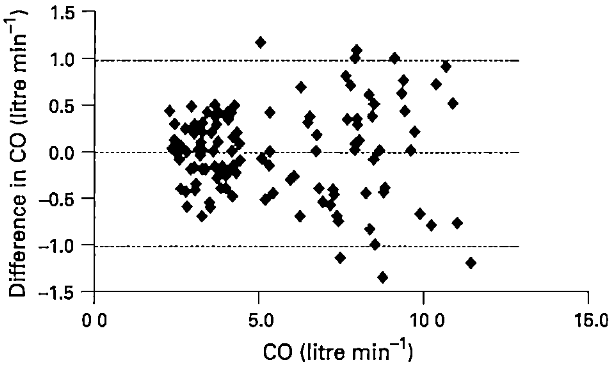

*Figure 1* Mean of simultaneous thermodilution and bioimpedance cardiac output (CO) values *vs* the difference between them. Mean difference (0.01 litre min$^{-1}$) and the limits of agreement (upper 1.01 litre min$^{-1}$, lower −0.99 litre min$^{-1}$) are shown as horizontal lines.

analysed according to the method described by Bland and Altman.[2] A plot of the differences between cardiac output measurements against the mean of the two measurements (fig. 1) showed no relationship between the measurement error and the true value (i.e. no consistent bias). The mean of the differences was 0.01 (SD 0.51) litre min$^{-1}$ and there was a Gaussian distribution of values. Therefore, 95% confidence interval of the differences was +1.01 (upper limit) to −0.99 (lower limit) litre min$^{-1}$ (SD 1.96); SEM was 0.042 litre min$^{-1}$. The precision of these estimated (mean, upper and lower) limits of agreement was derived using a $t$ test with 144 ($n-1$) degrees of freedom and calculating 95% confidence intervals for each of the limits. Thus the mean was 0.01 (SEM 0.08) litre min$^{-1}$. The 95% confidence interval for the other limits was similarly ±0.08 litre min$^{-1}$.

## Discussion

If an alternating current of constant magnitude is passed across the thorax, changes in impedance are related to variations in aortic blood flow, as air in the lungs, fat in the subcutaneous tissue and ribs traversing the muscles minimize conductance of these tissues. The outer four electrodes produce a constant high frequency current longitudinally across the thorax, generating a high frequency voltage in the same direction, which is proportional to the TEB. The inner electrodes sense changes in this voltage and the ECG, enabling changes in thoracic blood volume to be related to the cardiac cycle. The rate of change of impedance is used to calculate stroke volume, and from heart rate (detected by the ECG), cardiac output can be derived.[3]

The NCCOM3-R7 is simple to use. Four paired electrode pads are applied symmetrically to the chest, two at the base of the neck and the two in the middle of the sixth rib at the level of the xiphoid process. Careful positioning is needed as small changes in distance between cervical and thoracic electrodes may produce significant changes in stroke volume estimates. Beat-to-beat generation of data is possible, but makes assessment of changes and trends difficult; an averaging time of 10 s is more useful. ECG detection is the only difficulty we encountered using the NCCOM3-R7 and this was overcome using the extra pair of sensing electrodes supplied. As in humans, heart rates of greater than 175 beat min$^{-1}$ and arrhythmias were difficult for the NCCOM3-R7 to follow.

In studies comparing two methods of measurement, a Pearson product moment correlation coefficient is frequently quoted with a probability, as in the article of Spinale, Reines and Crawford ($r$=0.91 and $P$<0.001).[1] Despite the apparently impressive correlation, this is a poor analysis of two methods of measurement[2]: $r$ measures the strength of a relationship between two variables rather than agreement between them. Further, the strength of the correlation depends on the range over which cardiac output is measured and increases as the range increases. Most studies compare two methods over a large range of values (as we have done), almost guaranteeing a high correlation coefficient.

A simple and accurate alternative analysis, which is accepted widely as being more appropriate for such comparative studies, has been offered by Bland and Altman[2] and has been applied to our data. The mean of the measured cardiac outputs is plotted against the difference between these values (fig. 1). The mean of the differences can be calculated (in this case 0.01 litre min$^{-1}$), as can the SD (0.51 litre min$^{-1}$). The limits of agreement for TEB and TD were therefore ±1.0 litre min$^{-1}$ (95% confidence interval is calculated as mean ±1.96×SD). The precision of these estimates was determined using a $t$ test and the SEM to calculated 95% confidence interval as ±0.08 litre min$^{-1}$ (±1.96×SEM). There are two components to this error: within-technique and between-technique variability. TEB, unlike TD, is known to have a low within-technique variability (high level of repeatability),[4] perhaps because it averages a number of consecutive stroke volumes.[4] The between-technique variability should approach the within-technique variability for TD, that is <1 litre min$^{-1}$. Our data fell within this range and certainly the between-technique variability was far less than the within-technique repeatability reported by some groups for TD.[5] In the few studies using Bland and Altman statistics in humans, the quoted bias varied from −0.15 (SD 0.86)[6] to −0.7 (1.7).[4] Our results of 0.01 (0.51) compare favourably with these values. We can conclude that there is a high level of agreement between TEB and TD when allowance is made for the difference in chest geometry between the pig and humans, and that the variation is acceptably small.

# Effects on haemodynamics and catecholamine release of xenon anaesthesia compared with total i.v. anaesthesia in the pig

T. MARX, G. FROEBA, D. WAGNER, S. BAEDER, A. GOERTZ AND M. GEORGIEFF

## Summary

In order to investigate haemodynamic response and catecholamine release during anaesthesia with xenon, we conducted a study on 28 pigs which were allocated randomly to one of four groups: total i.v. anaesthesia with pentobarbitone and buprenorphine, and xenon anaesthesia with inspiratory concentrations of 30%, 50% or 70%, respectively, supplemented with pentobarbitone. Haemodynamic variables were measured using arterial and Swan Ganz catheters. Depth of anaesthesia was monitored using spectral edge frequency analysis. Plasma concentrations of dopamine, noradrenaline and adrenaline were measured by high pressure liquid chromatography. All haemodynamic variables and plasma concentrations of dopamine and noradrenaline remained within normal limits. Adrenaline concentrations were reduced significantly in all groups. Xenon anaesthesia was associated with a high degree of cardiovascular stability. Significant reduction in adrenaline concentrations at inspiratory xenon concentrations of 30% and 50% can be explained by analgesic effects of xenon below its MAC value. (*Br. J. Anaesth.* 1997; **78**: 326–327)

**Key words**
Anaesthetics volatile, xenon. Sympathetic nervous system, catecholamines. Cardiovascular system, effects. Pig.

To investigate dose-dependent influences of xenon anaesthesia on haemodynamic variables and catecholamine release, we studied different concentrations of xenon in an animal experiment.

In a study performed with 70% xenon supplemented by fentanyl, heart beat frequencies (HBF), arterial pressure and plasma catecholamine concentrations were measured, and the data compared with values obtained during nitrous oxide anaesthesia. Increases in noradrenaline concentrations, decreases in plasma adrenaline concentrations and a tendency for the HBF to decrease were seen. The cumulative dose of fentanyl was reduced by 80% in the xenon group.[1 2] Cardiac contractility, monitored by transoesophageal echocardiography, was not influenced by xenon anaesthesia.[3]

## Methods and results

We studied 28 pigs, aged 12–16 weeks, weighing 34.5–42.9 kg which were allocated randomly to one of four groups: group 1, total i.v. anaesthesia; group 2, anaesthesia with inspiratory xenon concentrations of 30%; group 3, 50% xenon; group 4, 70% xenon. Anaesthesia was induced with a bolus dose of pentobarbitone 8 mg $kg^{-1}$ and buprenorphine 0.01 mg $kg^{-1}$ i.v. Neuromuscular block was produced with a single dose of alcuronium 0.25 mg $kg^{-1}$. Anaesthesia was maintained with a constant infusion of pentobarbitone 0.2 mg $kg^{-1}$ $min^{-1}$. The rate of infusion was adjusted to the level of anaesthesia. Depth of anaesthesia was assessed using a spectral edge frequency SEF95 monitor. Intermittent positive pressure ventilation was carried out using a partial rebreathing system and ventilation volume was adjusted to achieve normocapnia. Inspiratory and expiratory xenon concentrations were measured by mass spectrometry .

A Swan-Ganz catheter was placed via the right internal jugular vein and a cannula was inserted into the right femoral artery. After these procedures the animals were left unstimulated for 60 min. The femoral artery was then dissected by open surgery under anaesthesia according to the randomization. At the request of the Animal Care Commission, animals in the TIVA group received an additional analgesic dose of buprenorphine 0.01 mg $\cdot kg^{-1}$ before skin incision. In the xenon groups, no additional analgesia was given. Serum concentrations of adrenaline, noradrenaline and dopamine were measured using high pressure liquid chromatography (HPLC) (table 1). The detection limit of each catecholamine was 2 pg $ml^{-1}$; accuracy was 3.9% for noradrenaline, 5.2% for adrenaline and 5.0% for dopamine.

## Comment

We observed a significant reduction in plasma adrenaline concentrations during xenon anaesthesia, not only at inspiratory concentrations of approximately 1 MAC, but even at subanaesthetic concentrations of 30% and 50%. Because all animals in the xenon groups received significantly less pentobarbitone than

those in the TIVA group, although no additional buprenorphine was given, the decrease in adrenaline concentrations in the xenon groups may have been produced by the analgesic effects of xenon, even in concentrations below its MAC value.[4]

All haemodynamic variables were not influenced by xenon anaesthesia and remained at normal values for conscious pigs and during anaesthesia. Because infusion rates of pentobarbitone of up to 0.6 mg kg$^{-1}$ min$^{-1}$ are known not to influence mean arterial pressure and cardiac output,[5] the influence of additional pentobarbitone infusion on haemodynamic values may be regarded as unimportant in our study. Therefore, we found that xenon was an inhalation anaesthetic with little influence on the cardiovascular system. This may represent an important difference to other inhalation anaesthetics.[6]

# Pregnenolone sulphate and pregnenolone do not interact with 5β-pregnanolone- and hexobarbitone-induced anaesthesia in the rat

M. D. WANG, G. WAHLSTRÖM AND T. BÄCKSTRÖM

## Summary

We have studied the interaction of pregnenolone sulphate and pregnenolone with 5β-pregnanolone- and hexobarbitone-induced anaesthesia in male rats using an EEG threshold method. Burst suppression of the EEG of 1 s or more ("silent second" (SS)), was used as a criterion of deep anaesthesia. The effects of the steroid solvents albumin and β-cyclodextrin were assessed by dose–response curves. Despite a significant increase in hexobarbitone threshold dose in relation to increased doses of albumin, there was no correlation between albumin dose and hexobarbitone concentrations in serum, fat and brain tissues. There was no significant difference in threshold concentrations of hexobarbitone between controls given albumin and those pretreated with pregnenolone. In subsequent experiments, 20% β-cyclodextrin was used as steroid solvent and its volume was maintained at less than 3.0 ml $kg^{-1}$ during pretreatment. Neither pregnenolone sulphate nor pregnenolone significantly altered the potency of 5β-pregnanolone for induction of anaesthesia. Furthermore, there was no interaction of pregnenolone sulphate and pregnenolone on induction of anaesthesia when hexobarbitone was used for anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 328–331).

**Key words**
Anaesthetics i.v., pregnanolone. Anaesthetics i.v., hexobarbitone. Rat. Hormones, steroid.

The synthesis of steroid hormones in endocrine tissues begins with cholesterol side chain cleavage (P450scc) which converts cholesterol to pregnenolone (5-pregnen-3β-ol-20-one). 3β-Hydroxysteroid dehydrogenase/isomerase converts pregnenolone to progesterone. Progesterone metabolites that are reduced in the 5-position of the steroid molecule are very potent CNS depressants, particularly those with a 3α-hydroxy-20-ketone structure. 5β-Pregnanolone (3α-hydroxy-5β-pregnan-20-one) is a naturally occurring anaesthetic which accumulates in the brain and interacts with central $GABA_A$ receptors as agonist.[1] Pregnenolone and its sulphate ester pregnenolone sulphate have been shown to be synthesized in glial cells in the brain via side chain cleavage of cholesterol. Brain concentrations appear to be independent of gonadal and adrenal synthesis.[1] Electrophysiological studies revealed that pregnenolone sulphate interacts with the $GABA_A$ receptor as antagonist.[1] *In vivo*, Majewska and coworkers[2] found that pregnenolone sulphate antagonized barbiturate-induced anaesthesia in rats, while Melchior and Allen[3] observed that pregnenolone sulphate enhanced barbiturate-induced depression in motor activity without affecting anaesthesia. The aim of this study was to evaluate the interaction of pregnenolone and pregnenolone sulphate with 5β-pregnanolone- and hexobarbitone-induced anaesthesia. In addition, we investigated the effects of the solvents albumin and β-cyclodextrin on induction of anaesthesia.

## Methods and results

A previously described EEG threshold method (see Korkmaz, Ljungblad and Wahlström[4] for references) was used to induce anaesthesia with hexobarbitone and 5β-pregnanolone. Anaesthetics were infused into the tail vein at a constant dose rate. The EEG was monitored continuously via subcutaneous electrodes. The infusion was terminated when the first burst of EEG suppression for 1 s or more was noted (the "silent second", SS). The appearance of SS occurs at a deeper level of anaesthesia than loss of righting reflex. The amount of anaesthetic needed to induce SS was calculated and considered as the threshold dose. A dose rate curve was generated by repeated measurements of threshold doses with different dose rates. The dose rate which gave the lowest threshold dose at SS was defined as the optimal dose rate. Data are expressed as mean (SD) and software SPSS was applied for data analysis.

After obtaining Ethics Committee approval a preliminary study was carried out to examine the effect of the solvent, albumin, on hexobarbitone-induced anaesthesia. Thirty-five male, adult Sprague–Dawley rats (MOL:SPDR Möllegaard, Ll. Skensved, Denmark) (mean weight 574 (45) g, aged 300–310 days) were used and pregnenolone (Sigma, MI,

MING-DE WANG, MD, TORBJÖRN BÄCKSTRÖM, PHD, MD (Department of Physiology and Department of Obstetrics and Gynaecology); GÖRAN WAHLSTRÖM, PHD, MD (Department of Pharmacology); University of Umeå, S- 901 85, Umeå, Sweden.
Accepted for publication: November 6, 1996.

USA) was dissolved in human albumin (Novo Nordisk, Bagsvard, Denmark, 20 mg $ml^{-1}$) at a concentration of 0.7 mg $ml^{-1}$. Sodium hexobarbitone (Sigma, MI, USA) was prepared in 0.9% saline and infused at an optimal dose rate of 15 mg $kg^{-1}$ $min^{-1}$ established previously. The volume rate was 0.1 ml $min^{-1}$ (see Korkmaz, Ljungblad and Wahlström[4] for references). Fifteen minutes before infusion of hexobarbitone, rats were pretreated with pregnenolone 3.5–7.0 mg $kg^{-1}$ i.v. As a control, the albumin solution was used to pretreat rats at equivalent volumes. The infusion volume rate for pretreatment was 1 ml $min^{-1}$.

A significant increase in hexobarbitone threshold dose was observed from 54.0 (8.4) mg $kg^{-1}$ in untreated rats to 108.6 (19.4) mg $kg^{-1}$ for the highest dose of pregnenolone pretreatment ($F_{2,18}$= 7.03, $P<0.05$). An increase in hexobarbitone threshold from 54.0 (8.4) mg $kg^{-1}$ in untreated rats to 103.4 (12.8) mg $kg^{-1}$ in rats given the highest volume of albumin was also found in albumin controls ($F_{2,19}$=22.86, $P<0.05$). Two-way ANOVA revealed no significant difference in threshold doses of hexobarbitone between pregnenolone pretreated rats and controls ($F_{2,19}$=0.05, $P$=0.96). The rats were killed at SS and hexobarbitone concentrations in serum, fat, occipital cortex, cerebellum, mid-brain and medulla oblongata were measured by HPLC and UV spectrophotometry, essentially according to a method described in detail previously.[4] Although there was a significant increase in hexobarbitone threshold doses in relation to increased dose of albumin, there was no significant correlation between albumin dose and hexobarbitone concentrations in serum, fat and brain tissues for either controls or pregnenolone pretreated rats (fig. 1). Furthermore, there was no significant difference in hexobarbitone concentrations in any tissue between controls and pregnenolone pretreated rats ($F_{3,85}$=1.71, $P$=0.17, two-way ANOVA).

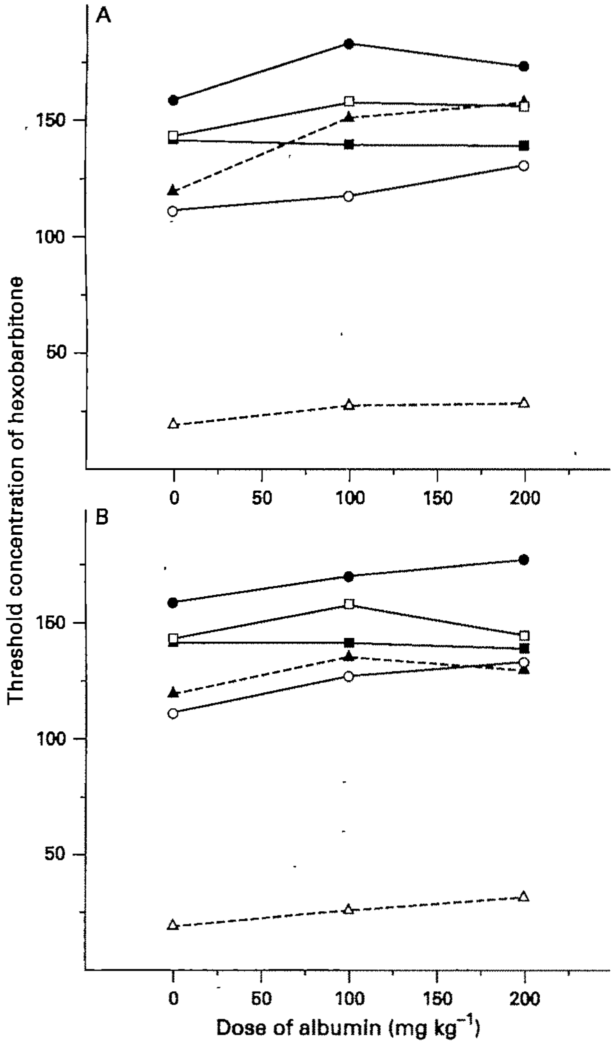

*Figure 1* Relationship between threshold concentrations of hexobarbitone at silent second (serum μg $ml^{-1}$, fat and brain tissue μg $g^{-1}$) and dose of albumin in vehicle controls given albumin (A) and rats pretreated with pregnenolone (B). ▲=Serum; △=fat; ●=medulla oblongata; ○=midbrain; ■=occipital cortex; □=cerebellum.

We used 130 male rats (mean weight 328 (12) g, aged 65–70 days) to examine the interaction of pregnenolone and pregnenolone sulphate (Sigma, MI, USA) with 5β-pregnanolone- (CoCensys, Inc., Irvine, CA, USA) induced anaesthesia. Pregnenolone 5.0 mg $ml^{-1}$, pregnenolone sulphate 6.0 mg $ml^{-1}$ and 5β-pregnanolone 4.0 mg $ml^{-1}$ were dissolved in 20% β-cyclodextrin (Sigma, MI, USA) (β-cyclodextrin 2.0 g in 10 ml of distilled water) in 15-ml aliquots. They were placed in the Bransonic 2210 ultrasonic bath for 15 h and agitated occasionally. After exposure to sonication, all steroids were wetted by visual inspection. Cyclodextrins are cyclic oligosaccharides consisting of 6–8 glucose units which can form inclusion compounds with guest molecules and thereby improve drug solubility and bioavailability.

The relationship between threshold doses of 5β-pregnanolone at SS and dose rate used for infusion of 5β-pregnanolone was determined ($n$=14). The volume rate of the 5β-pregnanolone infusion was 0.35 ml $min^{-1}$. Three dose rates (2.0, 3.0, 4.0 mg $kg^{-1}$ $min^{-1}$ ) were tested. A dose rate of 3.0 mg $kg^{-1}$ $min^{-1}$ was defined as the optimal dose rate. In a control experiment, rats were pretreated with 20% β-cyclodextrin i.v. at volumes of 3.0, 6.0 and 12.0 ml $kg^{-1}$, 15 min before infusion of 5β-pregnanolone ($n$=25). A significant increase in 5β-pregnanolone threshold doses was observed at SS which was related to the volume of β-cyclodextrin ($F_{3,24}$=9.62, $P<0.005$, two-way ANOVA). However, 5β-pregnanolone threshold was not significantly altered by 20% β-cyclodextrin pretreatment at 3.0 ml $kg^{-1}$ compared with untreated controls (least- significant difference test). In order to avoid an effect of the vehicle, the amount of β-cyclodextrin used during pregnenolone and pregnenolone sulphate pretreatment was maintained at less than 3.0 ml $kg^{-1}$. Doses of pregnenolone 3.5, 7.0 and 14.0 mg $kg^{-1}$ were tested. Pregnenolone sulphate pretreatment was performed at doses of 4.5, 9.0 and 18.0 mg $kg^{-1}$, which were equimolar to the corresponding doses of pregnenolone. Eight rats were used in each dose group. As a control, eight rats were pretreated with β-cyclodextrin 3.0 ml $kg^{-1}$ in both the pregnenolone and pregnenolone sulphate parts of

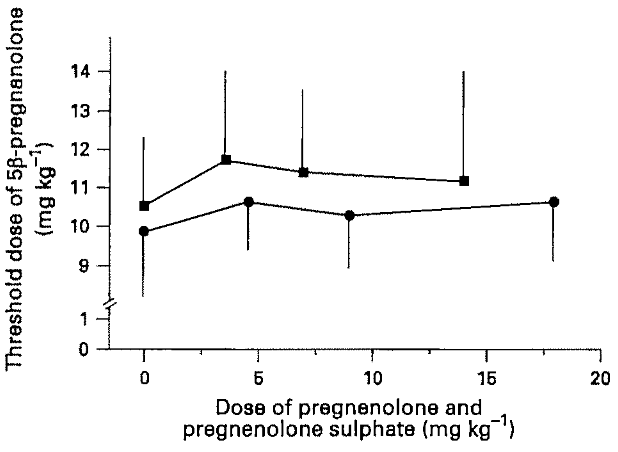

*Figure 2* Relationship between dose of pregnenolone (■) or pregnenolone sulphate (●) and threshold doses of 5β-pregnanolone at silent second.

the experiment. We found that neither pregnenolone nor pregnenolone sulphate significantly altered the threshold doses of 5β-pregnanolone at SS ($F_{3,27}$=1.07, $P$=0.38 and $F_{3,27}$=0.43, $P$=0.74, respectively) (fig. 2).

Doses of pregnenolone 14.0 mg kg$^{-1}$ ($n$=9) and pregnenolone sulphate 18.0 mg kg$^{-1}$ ($n$=9) were also used to study the interaction of the two neurosteroids with hexobarbitone-induced anaesthesia. As a control, nine rats were pretreated with β-cyclodextrin 3.0 ml kg$^{-1}$, 15 min before infusion of hexobarbitone. We found that the threshold doses and cortex concentration of hexobarbitone in the control group (111.3 (8.9) mg kg$^{-1}$ and 92.4 (4.7) μg g$^{-1}$, respectively) were not significantly different from those in the pregnenolone (117.5 (10.9) mg kg$^{-1}$ and 93.4 (8.5) μg g$^{-1}$) and pregnenolone sulphate (105.1 (13.7) mg kg$^{-1}$ and 90.0 (4.9) μg g$^{-1}$) groups.

## Comment

We have previously used a protein vehicle, albumin, as steroid solvent and observed that an albumin preparation of 5α-pregnanolone was more potent than its lipid preparation in inducing anaesthesia.[5] When we investigated the effect of albumin on the anaesthetic potency of hexobarbitone, threshold doses of hexobarbitone at SS increased in the pregnenolone treated group in the same way as in the control group given the corresponding volume of albumin. However, hexobarbitone concentrations in plasma, fat and four parts of the brain did not change significantly. This indicated that brain sensitivity to hexobarbitone was stable regardless of the increasing doses of albumin. Albumin as a vehicle might cause volume expansion of the blood compartment, thereby diluting the CNS depressant drug in serum. Our results from an interaction study between pregnenolone, pregnenolone sulphate and hexobarbitone differed from those of Majewska and co-workers[2] who observed that pregnenolone sulphate 8.6–16.8 mg kg$^{-1}$ i.p. reduced pentobarbitone-induced anaesthesia time by 17–37%. Differences between results obtained when studying induction of anaesthesia compared with those from experiments examining anaesthesia time could be caused by several factors unrelated to changes in brain sensitivity in response to the agents tested, such as elimination rate of the anaesthetic, hypothermia, acute tolerance or pharmacokinetic properties of the substances used during pretreatment. These factors are unrelated to changes in brain sensitivity which may have been induced by the pretreatment.

If pregnenolone sulphate interacts with the steroid recognition site on the GABA$_A$ receptor complex and thus alters the sensitivity to anaesthetic agents acting on the GABA$_A$ receptor, it would be expected that the sensitivity to 5β-pregnanolone should be influenced more profoundly than that of barbiturates.[1] However, we studied the influence of pregnenolone and pregnenolone sulphate on induction of 5β-pregnanolone-induced anaesthesia. However, we found no interaction despite maximal doses clearly within the range used by Majewska and co-workers.[2] The interval between pregnenolone sulphate pretreatment and infusion of 5β-pregnanolone may be critical for drug interaction. Therefore, we have also studied intervals of 5, 15, 30 and 45 min between pretreatments and 5β-pregnanolone infusions. The threshold doses at SS did not differ significantly between rats with different delay times (data not shown). The lack of effects in our rat strain could be a result of minimal brain extraction of pregnenolone sulphate because of its low lipophilicity. However, determination of pregnenolone sulphate at SS revealed a concentration of up to 200 ng g$^{-1}$ in some brain parts in rats pretreated with pregnenolone sulphate 18.0 mg kg$^{-1}$ (data not shown). This is the concentration at which pregnenolone sulphate may be expected to have effects on the CNS.[6] Furthermore, this concentration of pregnenolone sulphate was approximately 100 times less compared with brain concentrations of 5α-pregnanolone, a steroid anaesthetic related to 5β- pregnanolone, at induction of SS with a dose of 8 mg kg$^{-1}$.[5] Thus it was not strange that no interaction was observed between pregnenolone sulphate and 5β-pregnanolone.

Another possibility which could explain the dose-dependent antagonistic effect of a pregnenolone sulphate solution is that the vehicle could have increased the volume of the blood compartment, not only in our experiments, but also in those of Majewska and co-workers.[2] Pregnenolone sulphate has been reported to interact with the GABA$_A$ receptor in a manner opposite to that of 5β-pregnanolone in the micromolar concentration range.[1] However, Gee, Joy and Belelli[6] demonstrated that pregnenolone sulphate at submicromolar concentrations had anticonvulsive activity in mice. Some steroids could have both excitatory and anticonvulsive effects in the CNS. It is also possible that the magnitude of the dose could be important as several CNS depressant drugs have excitatory effects at low doses.

# Antagonism of suxamethonium-induced jaw muscle contracture in rats

Y. SHI, R. J. STORELLA, M. M. KEYKHAH AND H. ROSENBERG

## Summary

Masseter muscle rigidity (MMR) induced during general anaesthesia by suxamethonium is a clinical problem that may interfere with tracheal intubation. We have investigated the relation between twitch tension and contracture response to suxamethonium in rats. Rats were anaesthetized with 1% halothane (1.35 MAC). Jaw muscle temperature was maintained at either 37 or 41 °C while rectal temperature was kept at 37 °C by radiant heat. Twitch tension was produced by nerve stimulation at 0.2 Hz. Rats were pretreated with either a low dose of vecuronium (0.03 mg kg$^{-1}$) or dantrolene (0.8 mg kg$^{-1}$). Thereafter suxamethonium 750 μg kg$^{-1}$ was administrated i.v. Low-dose vecuronium pretreatment significantly (90%) decreased suxamethonium-induced jaw muscle contracture (JMC) with minimal (3%) twitch block during local hyperthermia. Low-dose dantrolene pretreatment also reduced JMC (81% at 37 °C and 82% at 41 °C) while decreasing twitch by 30% at 37 °C and 31% at 41 °C. Both vecuronium and dantrolene at doses that minimally depressed the twitch response antagonized suxamethonium-induced JMC. We speculate that pretreatment with low-dose vecuronium decreases suxamethonium-induced MMR clinically. (*Br. J. Anaesth.* 1997; **78**: 332–333).

**Key words**
Anaesthetics volatile, halothane. Hyperthermia, malignant. Complications, masseter muscle rigidity. Neuromuscular block, suxamethonium.

Suxamethonium may produce masseter muscle rigidity (MMR) during induction of anaesthesia and cause difficulty in tracheal intubation.[1] Previous laboratory studies showed that suxamethonium can induce jaw muscle contracture (JMC) during halothane anaesthesia in rats. The interaction between local hyperthermia of the jaw muscle and halothane can greatly increase suxamethonium-induced JMC.[2 3] Vecuronium is a non-depolarizing neuromuscular blocking agent while dantrolene is used in the prevention and treatment of malignant hyperthermia (MH). The purpose of the study was to examine if low doses of vecuronium and dantrolene, which have minimal effects on twitch, can block JMC in the rat.

## Methods and results

The study was approved by the University Animal Welfare Committee. We designed two sets of experiments using similar methods. Male Wistar–Furth rats (278–440 g) were anaesthetized with 1% halothane (1.35 MAC). After tracheotomy and establishing mechanical ventilation, the right femoral vein was cannulated for drug administration. Isometric jaw muscle tension was recorded via a tension transducer connected to the lower incisors. Twitch tension was produced by bilateral supramaximal mandibular nerve stimulation (0.2 Hz). Jaw muscle temperature was maintained at 37 °C (normothermic) or 41 °C (hyperthermic) by radiant heat and monitored by a temperature probe (Mon-a-Therm 6501) which was secured into the left jaw muscle while rectal temperature was maintained at 37 °C by a heat lamp.

In preliminary experiments, the dose effects of vecuronium and dantrolene on twitch tension and suxamethonium-induced JMC were examined to obtain the correct doses which could maximally block JMC with minimal inhibition of twitch tension. In the first set of experiments vecuronium was tested. Rats were allocated randomly to one of two groups ($n=6$ each): vecuronium and control groups. Vecuronium 0.03 mg kg$^{-1}$ was administered i.v. 40 s before administration of suxamethonium 750 μg kg$^{-1}$. Saline was injected i.v. before suxamethonium injection in the control group. Jaw muscle temperature was maintained at 41 °C with rectal temperature kept at 37 °C. In the second set of experiments, dantrolene was tested. Rats were allocated randomly to one of four groups ($n=6$ each): control hyperthermic, control normothermic, dantrolene hyperthermic and dantrolene normothermic groups. Dantrolene 0.8 mg kg$^{-1}$ or saline was administered i.v. 5 min before administration of suxamethonium 750 μg kg$^{-1}$ i.v. The percentage of twitch tension block by vecuronium or dantrolene and peak contracture after suxamethonium were measured. Data

*Address for correspondence: Department of Anesthesiology, MS 310, MCP and Hahnemann University, Broad and Vine, Philadelphia, PA 19102, USA.

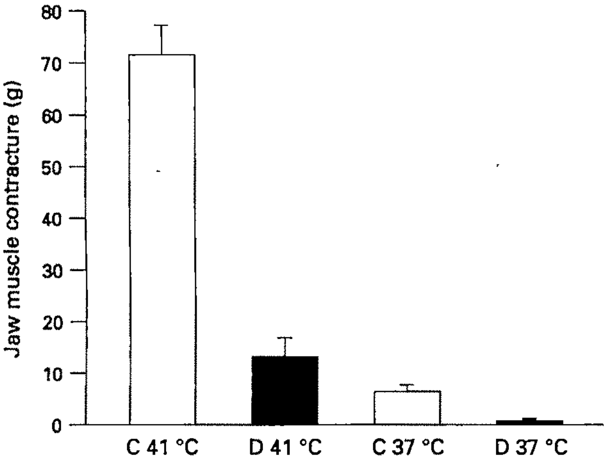

*Figure 1* Suxamethonium-induced jaw muscle contracture was significantly different among control hyperthermic (C 41°C), dantrolene hyperthermic (D 41°C), control normothermic (C 37°C) and dantrolene normothermic (D 37°C) groups. Both dantrolene and jaw muscle temperature had significant effects on the differences ($P<0.01$, ANOVA).

are presented as mean (SEM). Student's *t* test and two- factor ANOVA were used. $P<0.05$ was considered significant.

In the absence of pretreatment, suxamethonium produced JMC. Low-dose vecuronium (0.03 mg $kg^{-1}$) had a significant effect on JMC but little effect on twitch. Compared with control, suxamethonium-induced JMC was reduced by approximately 90% (48 (7.3) *vs* 4.7 (1.0) g; $P<0.01$, *t* test). In contrast, twitch tension was blocked minimally (3 (1.5) %) by vecuronium.

Low-dose dantrolene (0.8 mg $kg^{-1}$) also had a significant effect on JMC but modest effect on twitch (fig. 1). Compared with the control groups, dantrolene pretreatment reduced suxamethonium-induced contracture by 81% (1.3 (0.1) *vs* 7.0 (1.1) g) under normothermic conditions and by 82% (13 (4.4) *vs* 72 (6.3) g) under hyperthermic conditions ($P<0.01$, ANOVA). Twitch tension block by dantrolene was also similar in both hyperthermic and normothermic groups (31 (2.6) *vs* 30 (1.7) %). As elevation in jaw muscle temperature increased suxamethonium-induced JMC by approximately 10-fold in both the control (7.0 (1.1) *vs* 72 (6.3) g) and dantrolene (1.3 (0.1) *vs* 13 (4.4) g) groups, dantrolene 0.8 mg $kg^{-1}$ did not alter the temperature dependent effect of suxamethonium-induced JMC.

## Comment

Dantrolene is used in the prevention and treatment of MH. We found that low-dose dantrolene (0.8 mg $kg^{-1}$) pretreatment also greatly inhibited suxamethonium-induced JMC while only modestly blocking twitch. Interestingly, the percentage diminution of JMC was similar both with and without dantrolene pretreatment, indicating that dantrolene does not alter the temperature dependence of suxamethonium-induced JMC.

Vecuronium is often used in low doses to reduce the cholinergic agonist action of suxamethonium (i.e. fasciculations). We found that low-dose vecuronium (0.03 mg $kg^{-1}$) pretreatment, which only minimally affected twitch, almost completely blocked suxamethonium-induced JMC. The explanation for the greater sensitivity of suxamethonium-induced contracture than twitch to vecuronium may be that JMC is caused by a halothane–suxamethonium interaction at extrajunctional receptors, as contracture is more sensitive to non-depolarizing block than twitch because the latter has a "margin of safety".[4]

Smith and colleagues[5] reported that increases in muscle tension of approximately 50% are a normal response to suxamethonium in children and suggested that MMR may be considered as an exaggerated form of the normal pharmacological effect of suxamethonium. Smith and colleagues found that a sub-paralysing dose of tubocurarine (0.05 mg $kg^{-1}$) was ineffective in preventing the increase in suxamethonium-induced masseter muscle tension in children. If we consider that the contracture at normal jaw muscle temperature is a "normal response" to suxamethonium, it is reasonable to propose that the contracture at elevated jaw muscle temperature (which is 10-fold the contracture at normal temperature) is an "exaggerated response" to suxamethonium. Therefore, we believe that our findings are more relevant to generation of MMR.

We conclude that both dantrolene and vecuronium, at doses that minimally depressed twitch response, antagonized suxamethonium-induced JMC. JMC may be mediated by extrajunctional acetylcholine receptors in rats. We also speculate that pretreatment with small doses of vecuronium decreases suxamethonium-induced MMR clinically.

CASE REPORT

# Lumbovertebral syndrome after repeat extradural blood patch

J. H. McG. Palmer, D. W. Wilson and C. M. Brown

## Summary

We describe an obstetric patient who developed incapacitating headache after inadvertent dural tap and was treated with repeated blood patching. She subsequently developed severe lumbar back pain which, after exclusion of suspected extradural abscess, was treated successfully with simple analgesics and physiotherapy. Two possible explanations are offered to account for her symptoms. We compare this case with others in the literature. (*Br. J. Anaesth.* 1997; **78**: 334–336)

**Key words**
Anaesthetic techniques, extradural. Complications, lumbovertebral syndrome. Anaesthesia, obstetric.

## Case report

A 39-yr-old woman was admitted for elective lower segment Caesarean section (LSCS) at 36 weeks' gestation. She was seen by an anaesthetist before operation and decided to have the procedure under regional anaesthesia. During the performance of lumbar extradural block an inadvertent dural tap occurred. On the advice of the consultant anaesthetist present, the extradural catheter was introduced into the subarachnoid space, an intrathecal block performed using 0.5% "heavy" bupivacaine 2 ml, and continuous spinal infusion of 0.125% bupivacaine 2 ml $h^{-1}$ containing fentanyl 1 $\mu g$ $ml^{-1}$ started. This resulted in a good block to cold sensation extending from T3/4 to S1 bilaterally. This procedure and subsequent Caesarean section were uneventful and the patient was allowed to return to the postnatal ward with advice to remain supine for several hours, and she received laxative therapy and a generous i.v. fluid therapy regimen (3800 ml over the next 24 h). The spinal infusion was continued for 12 h at which time, because of the change in level of anaesthetic cover at that time (23:00), i.v. PCA morphine was started and the spinal catheter removed. She was reassessed at this time and had neither symptoms of post-dural puncture headache (PDPH) nor pain. However, later the following day she developed both frontal and occipital headache with neck pain and 48 h after LSCS the decision was taken to perform extradural blood patching. This was performed by a consultant using 12 ml of autologous blood at the same lumbar interspace (L3/L4) as the dural tap, with immediate improvement in her symptoms. Blood was taken for cultures at the same time. After this the patient remained recumbent for 1 h.

Follow-up of the patient by anaesthetic staff showed an encouraging improvement of her headache with only very mild symptoms, allowing her to function normally, but 2 days later, just before discharge, the same headache abruptly recurred. Physical examination at this time was unremarkable with no local back problems, pyrexia or cranial nerve signs.

She was treated conservatively for a further 48 h with no improvement in symptoms and after further discussion repeat blood patching was performed. This was also performed by a consultant anaesthetist, on this occasion using the interspace above and an increased volume of 17.5 ml of autologous blood. Blood for cultures was again obtained at this time.

She did not obtain complete relief of her headache immediately, but she did report considerable improvement which allowed her to nurse her baby and return to full mobility. Anaesthetic follow-up at the time of discharge the following day showed continued improvement in her PDPH symptoms. She was instructed to return to the anaesthetic clinic 3 days later and encouraged to report daily by telephone to the on-call anaesthetic team.

At her clinic appointment she reported that her headache had disappeared, but that she had developed intermittent bilateral buttock pain, which made it difficult to walk. She also said she became "very sweaty" when walking. The consultant examining her found no positive physical signs and advised her to use simple analgesics and contact us if the problem did not resolve. She telephoned the consultant on-call 48 h later, obviously in severe distress, and complaining of severe back pain which she described as being low down "in her bottom" with radiation to the front of her thighs. This pain came on with walking, lasted only a few seconds, but was so excruciating that she would collapse without assistance. She was asked to come in immediately for review.

She was questioned and described little or no pain while seated or recumbent, but that the pain would come on suddenly if she rose from a chair, and

J. H. McG. Palmer, BSc, MB, ChB, FRCA, D. W. Wilson, MB, ChB, FRCA, C. M. Brown, MB, BS, FRACGP, Department of Anaesthesia, Caboolture Hospital, Caboolture, Queensland 4510, Australia. Accepted for publication: October 14, 1996.

would increase in severity after she took a few steps. She described the pain as being of a throbbing nature, similar to a very strong cramp but without any shooting character. The pain extended across the upper buttocks and radiated into the anterior thighs. She stated it was the pain in her back rather than weakness of the legs that caused her to collapse. She had no fever or rigors but reported diaphoresis with minimal exertion. She denied symptoms of urinary or faecal retention/incontinence and reported no paraesthesia. She was very distressed by the pain and frequently tearful.

On examination she had an awkward and hesitant gait limited by pain to a few steps and needed assistance to climb onto the examination couch. She was afebrile (37.1 °C) and the extradural puncture site was not tender, with no warmth, swelling or bruising present. Palpation of her back revealed tenderness over the L3, 4, 5 facet joints, particularly on the left, and marked left paravertebral muscle spasm. Both sacroiliac joints were non-tender on springing the pelvis. Straight leg raising was diminished on both sides and restricted to 45°, with pain in the back preventing further hip flexion. The pain was not exacerbated by ankle dorsiflexion, which suggested it was not caused by nerve root compression or disc prolapse. Reflexes, tone and sensation were normal in both lower limbs. She had reduced back flexion to approximately 80°, but extension, lateral flexion and rotation were normal.

Both x-rays and CT scan of her lumbar spine were normal, as was her full blood count. Blood cultures performed at the time of patching were negative.

A provisional diagnosis of back pain caused by lumbar facet joint irritation was made and she was prescribed simple analgesics and referred for physiotherapy aimed at reducing the paravertebral muscle spasm and mobilizing her facet joints. She was given a full explanation of her problem and reassured about worries she had of a more serious cause for her symptoms.

She showed marked improvement with physiotherapy, to the extent that she was discharged from the physiotherapy outpatient clinic after three visits. At follow-up by telephone 1 month later she was cheerful and reported no headache, good mobility and minimal back symptoms brought on by awkward posture which were similar to the non-specific back pain she had suffered as a typist a few years previously.

## Discussion

Inadvertent dural puncture occurs in approximately 1.3% of obstetric extradurals, the rate being affected by the experience of the operator and factors relating to the technique and patient.[1] In our case the patient significantly exceeded her ideal weight (113 kg for a height of only 166 cm) which made extradural puncture difficult and the extradural was sited by an SHO who had performed 150 extradurals. The rate of PDPH with a 16-swg Tuohy needle has been reported as 81%.[1] Extradural blood patching is most successful if used after conservative methods have failed rather than as a prophylactic measure, when success rates are lower,[2 3] although this has not been found by all investigators.[4] The optimum volume of blood to use remains a choice for the individual anaesthetist, with volumes of 5–15 ml being common[2–6] and one study[5] found no benefit in exceeding 10 ml. Overall the success rate of a first blood patch is high, with up to 96% of patients reporting complete initial disappearance of symptoms and 86–89% of patients satisfied 4 weeks after their first patch even if the headache had not completely gone.[5] After failure of a first blood patch the choices are less obvious, with some authors recommending repeat patches, others normal saline infused extradurally[6 7] and even the use of extradural dextran infusions.[8] We chose the repeat patch as the first had been initially successful. There are reported cases of back pain after initial blood patching[9–11] but we could find only one which closely resembled ours. In their article[9] Seeberger and Urwyler described the case of a 40-yr-old woman with remarkably similar symptoms. She also had a previous history of low back pain, had been in a clerical occupation and her pain after blood patching matched the extent and distribution in this case, particularly radiation to the anterior thigh. The two women both complained of sweating, although in their case this was nocturnal.

The major differences were that their patient was non-obstetric and had a unilateral plaster cast which, together with the abnormal gait caused by the use of crutches, was thought to be a possible cause of the back pain. They also believed that the relatively large volume of blood injected (25 ml) might have been a contributory factor. In our case the second blood patch volume was 17.5 ml and the initial blood patch was 12 ml, both well below the volume used by Seeberger and Urwyler and would tend not to support their view. One other possible cause for back pain has been suggested by Beards and colleagues[12] who demonstrated by magnetic resonance imaging extensive subcutaneous spread of blood after blood patching. They felt this might contribute to back pain.

The immobilization of our patient for the purpose of initial conservative treatment, prolonged after failure of the first blood patch, may have also encouraged abnormal back posture, which ultimately caused the facet joint irritation symptoms. In addition, daily visits by an anaesthetist and our obvious concern about her recovery may have reinforced any emotional factors thus exacerbating her symptoms. Back pain after childbirth is a well recognized and frequent complaint. One study of more than 1000 women who were questioned about back pain with onset before or during pregnancy or with onset post-partum, revealed that the overall incidence of back pain 1–2 months post-partum in this population was 44%. Predisposing factors were a previous history of back pain, younger age and greater weight.[13] For those with new onset post-partum back pain, predisposing factors were greater weight and shorter stature. Our patient fitted into this category.

In conclusion, we suggest that for those women likely to develop back pain post-partum who require extradural blood patching, prophylactic physiotherapy and information on posture and lifting should be offered. Also, in this group of women, it would seem sensible to avoid immobilization as part of the conservative treatment of PDPH.

# CORRESPONDENCE

## Removal of LMA in children

Sir,—The article of Kitching, Walpole and Blogg[1] investigating removal of the laryngeal mask in anaesthetized and awake children merits further discussion. At our hospital we routinely use the laryngeal mask airway (LMA) in the general paediatric population for various ear, nose and throat (ENT) procedures.[2] Our standard practice is in accordance with those of both the inventor and the manufacturer of the masks.[3] The LMA is left *in situ* until the patient regains protective airway reflexes unless problems arise before this time requiring active airway management. We agree that children have an increased incidence of airway complications when recovering from anaesthesia compared with the adult population[4] and appreciate the challenging period this can be. For this reason we have conducted a prospective audit into the clinical use of the LMA at our hospital. As part of this we have examined specifically the recovery phase of anaesthesia with the LMA in paediatric patients. This information should add to the debate which this article will generate.

Currently we have audited 140 paediatric patients aged 1–14 yr old, weighing 5–45 kg, undergoing routine ENT procedures. Anaesthesia was induced with propofol i.v. in 112 cases and sevoflurane in the remaining 28 patients. Each LMA was inserted by the classical method, as described by Brain,[3] and only reinforced masks[5] sizes 2, 2.5 and 3 were used. All were left *in situ* at the end of the procedure to allow full return of airway reflexes and any airway complications before or after removal of the LMA were noted. A record was also kept of who removed the mask and depth of anaesthesia on removal.

A total of 126 (90%) children had a totally uneventful recovery period with no airway complications. In those cases where complications occurred, the commonest problem was either coughing or retching associated with impending mask expulsion by the patient. The overall incidence of airway complications with the LMA during recovery was as follows: seven (5%) patients coughed, four (3%) retched and three (2.5%) had laryngospasm. There were no episodes of aspiration or loss of airway. The LMA was removed by the child in 28 (22%) cases, recovery nurse in 89 (70%) cases and the anaesthetist in nine (8%) cases. None of the masks was removed at a deep stage of anaesthesia; the conscious level of the patient on removal of the LMA was recorded as light (i.e. responded to physical stimulation but inappropriate response to verbal command) in 36 (28%) cases and awake (i.e. appropriate response to verbal commands) in 90 (72%) cases. The three cases of laryngospasm occurred in patients undergoing adenotonsillectomy and all presented soon after cessation of anaesthesia, with the LMA being removed by the anaesthetist in two of these cases. In two patients the LMA lodged in the oropharynx on attempted removal but in both cases the mask was soon extricated with gentle manipulation. One case of partial airway obstruction occurred when the child displaced the bite block and consequently bit on the LMA tube; this resolved on awakening. Only three (2%) patients required the LMA to be replaced with an oral tracheal tube for either inadequate airway maintenance or mechanical problems during the procedure.

The results of our ongoing audit on the use of the LMA in the ENT paediatric population shows a lower overall incidence of airway complications than the study by Kitching, Walpole and Blogg. Our values bear more relation to those of Mason and Bingham[6] who studied the use of the LMA in 200 paediatric patients. They reported 12 (6%) cases of coughing, 11 (5.5%) of biting, five (4%) of laryngospasm, four (4%) of retching and three (3.5%) of vomiting during the recovery phase. These authors left the LMA *in situ* in all cases until return of laryngeal reflexes and expulsion of the mask by the patient. Laffon and colleagues[7] investigated airway complications after anaesthetized compared with awake removal of the LMA in 60 children. This study demonstrated a lower incidence of airway complications in both the anaesthetized and awake groups than the study of Kitching, Walpole and Blogg and, more importantly, detected no significant difference between the two groups in individual airway complications. Again, in this study, the LMA remained *in situ* until the children demonstrated recovery of airway reflexes and had opened their eyes or mouth. Both of these previous studies and our current LMA audit have demonstrated a lower incidence of airway complications with the LMA during recovery than the study of Kitching, Walpole and Blogg. Several reasons may explain this variation in clinical experience with the LMA.

First, the LMA was removed when the child had awakened *sufficiently to swallow*. We contend that this depth of anaesthesia does not equate with either full return of airway reflexes or an awake state. The presence or return of swallowing in the anaesthetized patient with the LMA *in situ* is associated with an inadequate or "light" depth of anaesthesia.[8] The mask was therefore removed at too early a stage in the recovery process, associated with increased airway reflexes and complications. Second, the authors failed to mention if the LMA cuff was deflated before removal. Brain has stated previously that it is best to leave the cuff inflated until the mask is ejected spontaneously and to monitor cuff pressure via the pilot balloon during recovery.[9] A third possible cause of airway stimulation might have been inadequate peroperative analgesia as not all children received a caudal anaesthetic and the number in each group receiving such analgesia was not clearly stated. The study design also included rectal diclofenac on arrival in the recovery room but because of the rapid recovery time of sevoflurane[10] the children may have been in a light plane of anaesthesia while the suppository was administered. Any form of stimulating procedure at such a stage of anaesthesia can be associated with reflex airway responses. Finally, the authors failed to mention one of the major advantages offered by the LMA during recovery, namely maintenance of a patent airway thus decreasing the incidence of airway manoeuvres required during this period.[2] The importance of this benefit cannot be over-stated.

Avoidance of coughing and retching during recovery from ENT and plastics anaesthesia is important in order to prevent venous congestion and the potential for subsequent haemorrhage. ENT practice is associated with a higher incidence of airway complications than other areas of anaesthesia and the need for airway control in this group of patients is critical if such problems are to be avoided. We suggest from our experience that the LMA should be left *in situ* at the end of operation and remain so until it is expelled spontaneously by the awake child. There is a need for increased education of recovery staff in the correct management of the recovery phase with the LMA and non-intervention, avoiding excessive stimulation and suctioning is recommended if the full potential of the LMA is to be achieved.

Sir,—We thank Drs Parry, Glaisyer and Bailey for their interest in our article and for raising some points of difference between us.

The patients in our study received a "standardized" anaesthetic. Children who could not have the particular anaesthetic technique were excluded. All children had inhalation induction with halothane as we wished to eliminate the different effects on airway irritability possessed by various i.v. induction agents and other volatile agents. Because all patients were undergoing a plastic surgery procedure on the perineum or lower limb, a caudal or local block was performed for intraoperative and postoperative pain relief. We encountered no problems with insertion of the diclofenac suppositories in either the "deep" or "awake" group, probably because of the block. The entire anaesthetic technique was designed to make the time of removal of the LMA the only variable. The cuff was deflated before removal. Sevoflurane was not available.

Although Parry, Glaisyer and Bailey described a lower overall incidence of airway problems than in our study, we noted that two of their 140 patients required tracheal intubation whereas none of our 60 children did. However, patients in our study differed from those reported by Parry, Glaisyer and Bailey in being younger, not undergoing airway surgery and all having had antisialogogue premedication (oral atropine). Monitoring in the recovery period differed between these studies as all of our patients had continuous observation by one of the authors in addition to pulse oximetry. It is regrettable that Parry, Glaisyer and Bailey did not provide objective evidence of continued adequate oxygenation from $Sp_{O_2}$ measurements during recovery.

In our study of young children undergoing plastic surgery to the lower limbs and perineum, those in whom the LMA was removed at a deep plane had fewer coughing episodes compared with those removed on swallowing, however, coughing was not associated with other adverse respiratory events or hypoxia. In practice, swallowing normally immediately precedes wakefulness.

We agree that avoidance of coughing and retching is important in the recovery period to prevent complications such as haematoma formation After upper airway surgery, as Parry, Glaisyer and Bailey suggest, it may be best to leave the LMA *in situ* until the patient is awake, as any blood in the airway pools above the LMA and is scooped up on removal. Nonetheless, Parry, Glaisyer and Bailey removed the LMA before the child awoke in 28% of cases.

The lessons to be learned are that the LMA can be removed "deep" or at an "awake" plane, but coughing is most likely if swallowing reflexes have returned. When airway complications in the recovery phase are to be investigated, an anaesthetic technique should be chosen to reduce the number of variables to a minimum.

## Predicting difficulty—clinical indices and their statistical equivalents

Sir,—We were interested in the article by Ramadhani and colleagues[1] and their attempt to further familiarize clinicians with statistical definitions such as sensitivity, specificity, positive predictive values, etc, in respect of clinical tests for predicting difficult intubation. These definitions have appeared repeatedly in this type of article, despite being readily accessible in most statistical texts. The clear implication is that they are not intuitively obvious to clinicians and in presentations to our department we have suggested (slightly tongue in cheek) alternative clinical indices which may be considered to have more obvious clinical relevance and which may be described in terms of standard statistical definitions.

We need to start with some assumptions which although not necessarily clinically obvious also generally apply to standard statistical tests. First, prediction and difficulty assessment need to be considered as either easy or difficult with no indeterminate or intermediate categorization options. Second, we have to assume that these defined states are both absolute and universal (i.e. experienced and trainee anaesthetists would recognize the same classification and make the same judgements). Finally, we relate the proposed clinical indices to a non-Calman situation where the "on-call" trainee anaesthetist works without direct supervision and the experienced colleague is available to be called in from home.

For the trainee, clinical responsibility with regard to prediction of difficulty should end when difficulty is diagnosed. We expect the experienced colleague to come from home and deal with all such cases or at least take clinical responsibility for whatever happens From the trainee's point of view, continuing responsibility is important in respect of the cases predicted as easy. The trainee anaesthetist's nightmare (TAN) is the number of cases predicted to be easy but which turn out to be unexpectedly difficult relative to the total number predicted as easy. Referral to standard statistical definitions shows TAN=1−NPV (NPV=negative predictive value, the number of easy intubations correctly predicted relative to the total number of intubations predicted to be easy). In a similar manner, the experienced anaesthetist's tribulation (EAT) is the number of cases predicted to be difficult which turn out to be easy relative to the total number predicted as difficult. This refers to the number of times attendance for allegedly difficult intubations will in fact be inappropriate. Again this is defined as EAT=1−PPV (PPV=positive predictive value, the number of difficult intubations correctly predicted relative to the number of intubations predicted to be difficult).

These "worse case" clinical indices may help clarify the clinical relevance of the statistical definitions which obviously came first and were not defined specifically for predicting difficult intubation. Another "*aide-mémoire*" which clinicians may find useful for remembering the statistical definitions is the graphical square box description in Altman's book.[2] This text also describes the limitations of each of the statistical indices and the importance of considerations of prevalence for the condition to which they apply.

## Effect of amino acid infusion on body temperature during anaesthesia

Sir,—We were interested to read the study on the effects of preoperative infusion of amino acids in preventing postoperative hypothermia by Sellden, Bränström and Brundin.[1] We wish to comment on their conclusion.

The authors infused amino acid solutions (240 kJ $h^{-1}$) over 1–2 h before anaesthesia and compared the results with those from control patients who received saline, believing that preoperative administration of amino acids prevents anaesthesia-induced hypothermia.[1] In their previous study,[2] they suggested that peroperative amino acid infusion also prevented anaesthesia-induced hypothermia. In the present study,[1] they found that rectal temperatures increased significantly from the basal state during the first hour of amino acid infusion and decreased with the onset of anaesthesia. In the control group the decrease in temperature from the onset of anaesthesia was significantly greater than that in the amino acid-treated group.

We infused 335 kJ of amino acid solution during the first hour of anaesthesia to 25 patients and compared changes in nasopharyngeal and skin surface temperatures and the incidences of postoperative shivering with data from 25 control patients. In our study, nasopharyngeal and skin surface temperatures decreased in both groups during the first hour of anaesthesia. Nasopharyngeal temperatures decreased from 36.0±0.4 to 35.5±0.7°C in the amino acid-treated group and decreased from 36.2±0.4 to 35.7±0.5°C in the control group. Skin surface temperatures decreased from 32.2±1.2 to 32.1±2.1°C and from 32.4±1.6 to 32.5±1.7°C in the amino acid-treated and control groups, respectively. At the end of anaesthesia nasopharyngeal temperatures were 35.3±0.9°C in the amino acid-treated group and 35.5±0.7°C in the control group (ns). The incidences of shivering were similar in both groups (nine of 25 and seven of 25 in the amino acid-treated and control groups, respectively).

Our results do not confirm those of Selldén and collegues. Therefore, we believe that the effect of amino acid infusion on thermoregulation and its effect on preventing anaesthesia-induced hypothermia and postoperative shivering need further investigation.

2. Sellden E, Brundin T, Wahren J. Augmented thermic effect of amino acids under general anaesthesia: a mechanism useful for prevention of anaesthesia-induced hypothermia. *Clinical Science* 1994; **86**: 611–618.

Sir,—Donmez, Şekerci and Arslan reported that infusion of an amino acid solution (composition not reported) during the first hour of anaesthesia did not prevent postoperative shivering or anaesthesia-induced reductions in nasopharyngeal or skin temperatures in 25 patients. The authors argue that these findings do not correlate with two of our published studies in which we demonstrated that i.v infusion of a mixture of 19 amino acids (Vamin, Pharmacia Upjohn, Stockholm, Sweden) stimulated oxidative heat generation to an extent that effectively prevented whole body hypothermia and postoperative shivering. We have recently published further confirmation of these findings,[1] and wish to offer the following comment.

(1) We do not know how nasopharyngeal temperature was recorded or what this temperature represents. The reported basal values, 36.0 and 36.2°C, seem low compared with normal mixed blood or body core temperatures, (2) the observed average anaesthesia-induced reduction in nasopharyngeal temperature did not exceed 0.5°C in any of the groups. If this value represents the whole body temperature change, the observation would indicate that the anaesthetic agent used (not reported) did not induce clinically significant hypothermia in any group; (3) a reduction in body core or mixed blood temperature of 0.5°C would hardly be expected to induce much generalized shivering Nevertheless 30% of patients shivered in response to this average decrease in nasopharyngeal temperature. Although individual correlations between temperature and shivering were not presented, the finding might further suggest that the changes in nasopharyngeal temperature did not adequately reflect whole body temperature changes, (4) the shivering incidence of nine of 25 in the amino acid-treated patients seems surprising not only because of the small temperature reduction. We have never recorded postoperative shivering in any patient subjected to our mode of intraoperative amino acid treatment; (5) an unchanged skin surface temperature may be a reasonable finding in view of the well known centrifugal redistribution of heat during general anaesthesia.

We appreciate the interest of Donmez, Sekerci and Arslan in this field and would like to encourage the authors to continued studies including rectal, oesophageal or mixed blood thermometry.

## Anatomical configuration of the spinal column as determined by magnetic resonance imaging

Sir,— The anatomical configuration of the spinal column significantly affects the distribution of local anaesthetic solutions within the subarachnoid space. Hyperbaric anaesthetic solutions migrating cephalad, pool in the lowest region of the thoracic hollow under the influence of gravity[1] Textbooks of anaesthesia always describe that, in the supine position, the lowest point of the thoracic hollow is located at T5–6, a concept proposed by Barker in 1907.[2] However, no evidence exists to confirm this classical anatomical concept. We have demonstrated previously that the lowest point of the thoracic hollow determined by magnetic resonance (MR) imaging is located in the vicinity of T8 in Japanese healthy volunteers[3] and these findings do not agree with long-held concepts. However, differences in the curvature of the thoracic hollow may exist in subjects with different racial characteristics

Therefore, we attempted to examine sagittal MR images of the spinal column which are illustrated in MR imaging textbooks published in Europe and North America[4 5] There were no sagittal MR images to demonstrate that the lowest point of the thoracic hollow is located at T5–6. Of the eight images examined, the lowest point of the hollow was located at T7 in one, T8 in one, T8–9 in one, T9 in two, T9–10 in one and at T12 in two MR imaging provides precise anatomical information on the configuration of the spinal column in living subjects Consequently, the lowest point of the thoracic hollow in the supine position is unlikely to be located at T5–6, even in European and North American subjects.

## Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume

Sir,—We read with interest the article by Chung and colleagues[1] comparing different volumes of 0.25% hyperbaric bupivacaine for Caesarean section using spinal anaesthesia and wish to make the following points.

(1) Although the authors used different volumes of 0.25% hyperbaric bupivacaine for spinal injection according to patient height, there is no evidence that varying the dose of local anaesthetic in this manner affects the final characteristics of a spinal block.[2] If in this study patient height did indeed influence the spinal block, there would have been differences between subgroups given the same volume. For example, did the characteristics of the block with bupivacaine 3.6 ml given to the subgroup of patients in group 1 who were 161–165 cm in height differ from the subgroup of patients in group 2, 156–160 cm in height, given the same volume of local anaesthetic. Unfortunately no analysis of these subgroups was presented.

(2) The results of this study are also not related directly to the effects of volume of 0.25% hyperbaric bupivacaine as suggested, as the same concentration of local anaesthetic was used

throughout the study. Therefore, as the volume of the spinal injection changed, so did the total dose of drug administered. The effect of volume independent of the actual amount of drug administered intrathecally was not compared. Many workers have demonstrated that the dose of intrathecally administered local anaesthetic is more important than volume.[3 4] Furthermore, there is evidence from the literature that the major factor affecting intrathecal spread of local anaesthetic in pregnant women at term is movement of the patient after spinal injection.[5] This is thought to result from extradural venous engorgement, secondary to vena caval compression while the patient is being turned, decreasing the volume of the dural sac and thereby leading to displacement and spread of the local anaesthetic solution. A recent MRI study appears to support this theory.[6]

(3) We also question the accuracy of the sensory block assessments. From the data in table 3, it appears that surgery started and ended approximately 16 min and 83 min, respectively, after spinal injection. We deduce from figure 1 that during these 67 min of operating time, pinprick assessments were still continuing Presumably, according to the dermatomal levels recorded within this period, pinprick testing was continuing within the area of a supposedly sterile operating field. Or, inconceivably, were the surgeons also undertaking intraoperative sensory testing?

(5) Finally, considering the high incidence of hypotension in group 3, we would have expected umbilical cord gas tensions to have been measured.

Sir,—I thank Drs Bell, Fernando and Parry for their interest in our article.[1] Although the subgroups were small (only 10 cases), we analysed the differences in spinal block between all subgroups in groups 1 and 2, and groups 2 and 3, including subgroups given the same volume in different groups. There were no significant differences between all subgroups, except for subgroups with different heights, given different volumes. For example, the characteristics of spinal block with bupivacaine 3.2 ml in the subgroup of patients in group 1 who were 156–160 cm in height, differed from those with bupivacaine 4.0 ml in the subgroup of patients in group 2, 161–165 cm in height. The results support the concept that patient variables, especially height, are not important factors in determining the final characteristics of spinal block.[2]

Many workers[3 4] have demonstrated that the dose of intrathecally administered local anaesthetic is more important than volume or concentration in determining spread of anaesthetic solution in the CSF. However, other workers[5 6] have shown that increasing the volume administered into the subarachnoid space, especially with hyperbaric solutions, resulted in significantly greater cephalad spread. I agree that the effect of volume independent of the dose of drug administered intrathecally was not compared in our study. In the clinical dose range (10–15 mg) of 0.5% or 0.75% hyperbaric bupivacaine for spinal anaesthesia in Caesarean section, the volume does not exceed 3 ml. When 0.25% hyperbaric bupivacaine solution is used, a dose of 10–15 mg exists in a volume of 3.0–6.0 ml. The large volume of hyperbaric solution itself may influence the spread of local anaesthetics in CSF and final block, especially in the narrow subarachnoid space of the term parturient I think that the volume of hyperbaric spinal anaesthetic solution may be additive to the effects of gravity, position and dose.

As shown in tables 2 and 3, in all patients in groups 2 and 3, the regression times to T10 were more than 100 min and induction to end of surgery times were less than 85 min. Sensory block assessment was made easily in the flanks of patients without disturbing surgery in all patients in groups 2 and 3, but omitted during operation in approximately 50% of patients in group 1. However, the data did not influence the results, that is assessment of segmental spread of sensory analgesia (fig. 1) and regression time to T10 and L5 (table 2).

Umbilical cord blood analysis was not performed in this study and I think in retrospect that it would obviously have been better if these measurements had been made.

The aim of our study was to assess the safety and efficacy of 0.25% hyperbaric bupivacaine in glucose for spinal anaesthesia in Caesarean section. We found that if Caesarean section was undertaken with 0.25% hyperbaric bupivacaine for spinal anaesthesia, the volume required was at least 4.0 ml. Considering the quality of anaesthesia and incidence of hypotension, I think that 0.75% or 0.5% hyperbaric bupivacaine for spinal anaesthesia in Caesarean section is preferable to 0.25% hyperbaric bupivacaine.

## Management of rhabdomyolysis

Sir,—Tuckey reported on the management of a patient who developed rhabdomyolysis after bilateral calf compartment syndrome resulting from the lithotomy position.[1] Such patients are at great risk of developing renal failure and Tuckey correctly stated that this may be reduced by aggressively promoting an alkaline diuresis with i.v. infusions containing bicarbonate and mannitol While I agree that such vigorous therapy should be given to prevent or limit further morbidity and mortality, therapy itself carries significant risk on three accounts.

First, the recommended volume infusions (12 litre day$^{-1}$)[2] may result in fluid overload in an actual or potential critically ill patient. Second, bicarbonate infusion can produce metabolic alkalosis. Alkalaemia is associated with increased mortality.[3] In response to metabolic alkalosis, compensatory hypoventilation may occur. It has been suggested that the magnitude of this response is limited by the imposition of hypoxic drive.[4] However, patients have been described with metabolic alkalosis and life-threatening hypoxaemia and hypercapnia [5–7] Metabolic alkalosis also impairs the relationship between ventilation and perfusion in the lung[8 9] and limits systemic oxygen delivery by promoting leftward shift of the oxyhaemoglobin dissociation curve. Third, infusion of large doses of mannitol has been implicated in provoking renal failure.[10]

Rhabdomyolysis is a critical illness. Its treatment may cause serious complications. Management in an intensive therapy unit is indicated.

Sir,—I thank Dr Ball for his interest in my case report of a patient who suffered bilateral compartment syndrome after prolonged lithotomy position. The discussion included a description of the treatment of renal failure associated with rhabdomyolysis which should commence with appropriate cardiovascular resuscitation and prompt fluid therapy to encourage urine flow. The renal protective effect of alkalinizing the urine has been demonstrated and results from the fact that urate and myoglobin are more soluble in alkaline urine. In the report I quoted Better,[1] who suggested a very aggressive regimen of fluid containing bicarbonate and mannitol, as an example of management guidelines. I acknowledge all of Dr Ball's comments as valid, but I wish to reply to each point in turn.

(1) The aggressive fluid regimen of Better[1] must be tailored to the status and response of the individual patient, using appropriate invasive cardiovascular monitoring in the intensive care in the critically ill patient. Better has stated elsewhere that if myoglobinuric acute renal failure has occurred, with reduced renal output, solute load should not be given and regular haemodialysis is indicated.[2,3]

(2) Bicarbonate therapy has been controversial for many years. Bicarbonate is used in two main contexts; first, in the treatment of metabolic acidosis and second, to facilitate alkaline diuresis to enhance excretion of poisons.

Regarding the treatment of acidosis, Arieff proposes that metabolic acidosis with increased anion gap can be classified into those conditions in which tissue hypoxia is either present or absent.[4] In general, when there is metabolic acidosis in the presence of tissue hypoxia, available tissue oxygen is not adequate for the individual's needs. Treatment of metabolic acidosis with sodium bicarbonate tends to limit further available oxygen because of its effect on the position of the oxygen dissociation curve, and this leads to increased production of lactate thereby worsening the metabolic acidosis. Arterial $P\mathrm{CO}_2$ is directly proportional to production of carbon dioxide and inversely proportional to alveolar ventilation.[5] Thus increased generation of carbon dioxide by administration of bicarbonate increases venous $P\mathrm{CO}_2$ if there is impaired cardiac output (resulting in decreased delivery of venous carbon dioxide to the lungs), or decrease in alveolar ventilation. Carbon dioxide readily diffuses into cells such that intracellular $P\mathrm{CO}_2$ approaches that of mixed venous blood. In a closed system, carbon dioxide accumulates after administration of bicarbonate thereby decreasing intracellular pH.[6] Several workers have demonstrated the negative inotropic effect of bicarbonate on the ischaemic myocardium.[7–9]

However, sodium bicarbonate may be beneficial to patients with metabolic acidosis in the absence of tissue hypoxia.[10] Bicarbonate dialysis is tolerated better than acetate dialysis without cardiovascular instability, in critically ill patients with cardiorespiratory dysfunction,[11–13] possibly because of a direct effect on myocardial contractility[14] or through the effects of alkalosis on peripheral resistance.[15]

Bicarbonate may be used in alkaline diuresis to enhance excretion of toxins, including myoglobin and salicylates. In the treatment of crush syndrome, Better has advocated early volume replacement and, if urine flow commences, he recommends forced solute alkaline diuresis to prevent myoglobinuric acute renal failure.[2,3] Noji recommends a similar technique.[16] Likewise, in the treatment of salicylate poisoning, alkalinization has been shown to enhance excretion of the poison.[17,18]

(3) Mannitol. Some workers who have described mannitol nephrotoxicity syndrome have found that it occurs only after high doses of mannitol (e.g. $>200$ g day$^{-1}$) but not at lower doses [19,20] It may occur at slightly lower doses if patients have pre-existing impaired renal function.[21] It appears that at a low dose mannitol acts as a renal vasodilator, while in high doses it is a renal vasoconstrictor.[19,21] Mannitol-induced acute renal failure responds promptly to haemodialysis with rapid resolution of anuria and recovery of renal function.[19–21]

## Rocuronium and vecuronium

Sir,—Dr Schramm and colleagues demonstrated that rocuronium and vecuronium did not significantly affect intracranial pressure (ICP), MAP or CPP in a group of neurosurgical patients.[1] However, they then suggested that rocuronium may be used for neurosurgical patients without the risks associated with suxamethonium. Suxamethonium was not included in their study and the case against suxamethonium and adverse effects on ICP is probably overstated. Most studies have been performed on animals or on patients undergoing elective neurosurgery and should not be extrapolated to head injured patients, who are in the group most at risk from increased intracranial pressure.

In a recent prospective, randomized, double-blind crossover study, we compared the effects of suxamethonium or an equal volume of saline on cerebral haemodynamic state in 11 patients with severe head injuries.[2] All patients were sedated with i.v. infusions of propofol and morphine and their lungs ventilated mechanically in a regional neurosurgical intensive care unit. Mean age was 36 (range 17–70) yr and median GCS score 5 (range 3–8). Five patients had diffuse cerebral oedema, four were undergoing mechanical ventilation post-surgical evacuation of traumatic or subdural haematoma and two had traumatic intracerebral haematomas that did not require surgery. Mean baseline ICP was 12.5 (range 1–35) mm Hg and CPP 74.5 (55–96) mm Hg. There was no significant change in ICP or CPP after administration of suxamethonium or saline. This supports the work of Kovaric and colleagues who also showed no adverse effect of suxamethonium on ICP.[3] Rocuronium may have an onset of action approaching that of suxamethonium but its long duration of action makes it unsuitable for use as the first choice neuromuscular blocking agent in the management of patients with severe head injury when a full stomach is the rule rather than the exception. Suxamethonium remains the drug of choice for emergency intubation of severe head injuries with the proviso that it is preceded by adequate anaesthesia.

3. Kovaric WD, Mayberg TS, Lam AM, Mathisen TL, Winn HR. Succinylcholine does not change intracranial pressure, cerebral blood flow velocity or the encephalogram in patients with neurological injury. *Anesthesia and Analgesia* 1994; 78: 469–473.

Sir,—Regardless of the presence or absence of space-occupying intracranial lesions, suxamethonium in humans and animals produced significant increases in intracranial pressure (ICP) in many investigations. Lanier, Milde and Michenfelder[1] found that the increase in ICP with suxamethonium was accompanied by EEG arousal and an increase in cerebral blood flow (CBF). The increase in CBF was disproportionately greater than that expected from a concomitant increase in $Pa_{CO_2}$. In their subsequent study, they demonstrated that an increase in muscle spindle afferent activity paralleled the increase in CBF. Fasciculations in the muscles of the neck, causing stasis in the jugular veins, might also be a factor contributing to increased ICP with suxamethonium. Pretreatment with paralysing doses of pancuronium did not block afferent muscle activity or the CBF response. The increase in ICP was also not blocked by pretreatment with thiopentone.

In our institution we also studied the effects of suxamethonium on middle cerebral artery flow velocity using transcranial Doppler during intubation of the trachea in 10 head injured patients and found a significant increase in flow velocity after an i.v. bolus of suxamethonium (unpublished data until now). The mechanism of how suxamethonium influences ICP and CBF in humans remains uncertain. In contrast, there are as many studies concluding that ICP is not influenced by suxamethonium. Kovaric and colleagues[2] found that in brain-injured patients, suxamethonium did not alter cerebral blood flow velocity, cortical electrical activity or ICP. The literature on the effect of suxamethonium on ICP in animals and in humans has not provided firm indications that suxamethonium *per se* increases ICP Furthermore, inclusion of other drugs, differences in anaesthetic states and concurrent stimuli such as tracheal intubation further complicates analysis of the effect of suxamethonium on ICP. Increases in ICP seen with suxamethonium may also be caused by autoregulatory decreases in cerebral vascular resistance secondary to systemic hypotension. Braun and colleagues have made a valuable contribution to the literature, but despite many studies, including those of Braun and colleagues evaluating the effects of suxamethonium on ICP, controversy remains.

Respiratory problems and pulmonary infection frequently occur after head injury because of neurological dysfunction and laryngeal incompetence. Parr and Manara stated in their letter that rocuronium may have an onset of action approaching that of suxamethonium but its long duration of action makes it unsuitable for use as the first choice neuromuscular blocking agent in the management of patients with severe head injury. I cannot imagine any situation where early extubation of the trachea of a patient with severe head injury is planned and after intubation the clinical duration of action should be of minor concern as the effect of rocuronium on cerebral dynamics is not controversial. The only reason for the statement of Parr and Manara, therefore, is difficult airway management. Obviously we agree with them regarding patients with ileus, but those with severe head injury are at risk of aspiration with or without neuromuscular block. After intubation of the trachea of head injured patients using either vecuronium or suxamethonium, Redan and colleagues[3] concluded that paralysis and tracheal intubation in the emergency department is safe and may be a potentially life-saving manoeuvre in combat trauma patients. Nevertheless, a short onset of neuromuscular block is preferable as ventilation of the lungs of patients without intubation is risky. Intubation of the trachea of head injured patients in the emergency room should not be delayed as it may be for elective surgery or even for the patient with ileus. If intubation is impossible any other methods of airway access are required, for example emergency tracheotomy is indicated. Is suxamethonium superior because its duration of action lasts only a few minutes? The use of additional boluses of suxamethonium because of multiple intubation attempts may be accompanied by bradycardia, dual block and the other side effects of this drug.

## Intraoperative heat administration

Sir,—The study by Beck and colleagues[1] claimed that warming with a water perfused oesophageal heat exchanger was significantly more efficient at preventing intraoperative cooling than warming using ventilation with warm humidified gases, which was statistically ineffective compared with no heating. However, the study design leaves this conclusion in some doubt.

Approximately 75% of the benefit of ventilation with warm humidified gas (airway warming (AW)) arises from prevention of loss of heat and moisture which occurs during respiration, with the remainder comprising condensation of hot water vapour and a very small amount from the increased gas temperature.[2] These last components are very small using a temperature of 39 °C, and the system used provides only approximately 85% of the thermal gain possible with the temperature recommended for use in the treatment of accidental hypothermia (i.e. 45 °C).[2] Unfortunately, in the two other groups the patients' lungs were ventilated with cool (room temperature) humidified gas. This would provide approximately 65% of the benefit achievable through AW. The study therefore compared the effect of 85% AW with 65% AW and 65% AW plus the oesophageal water warming system. A fair evaluation of the thermal value of AW would have required the two other groups to undergo ventilation with dry gas.

The gas temperature of 45 °C was selected for use during treatment of accidental hypothermia to avoid thermal damage to the mouth, pharynx and larynx when the system is used with a face mask. Because of its ample blood supply the respiratory tract below the larynx is very resistant to thermal damage. For example a patient at 24.3 °C undergoing ventilation for 24 h with saturated gas at 80°C suffered only mild, reversible damage to the respiratory tract.[2] Temperatures of 350 °C with dry gas or steam at 94–104 °C are needed to cause burning to the trachea.[3 4]

Finally, while the oesophageal water circulating system has been used effectively in the treatment of accidental hypothermia, it has disadvantages in that the equipment is suitable only for hospital use; there is a danger if the thin rubber balloon bursts or tears and the GI tract is flooded with water; insertion of the tube may be impossible if the patient's teeth are clenched; and there is the risk of triggering VF during insertion of the tube. Airway warming can be used in the field and does accelerate the rate of rewarming to a statistically significant degree.[5]

5. Lloyd EL. Airway warming in the treatment of accidental hypothermia: a review. *Journal of Wilderness Medicine* 1990; 1: 65–78.

Sir,—We thank Dr Lloyd for his interesting comments on our recently published study.[1] As clearly stated both in the title and in the text, our goal was to evaluate the efficacy of two warming methods in a clinical intraoperative setting, under standardized conditions. For this reason we chose a temperature level (39 °C) that may be judged too low, but which is higher than the usual temperature (30–34 °C) used during clinical anaesthesia. Moreover, we had to modify the Kontron Pearl humidifier that in its standard configuration for human use cannot exceed the 37 °C limit. We were definitely not willing to use the high temperature used by some for treating severe accidental hypothermia.

According to Hendrickx, Trahey and Argentieri[2] heat lost by one of our pigs (34 °C) undergoing ventilation at a $\dot{V}E$ of 4 litre min$^{-1}$ in dry air–oxygen at room temperature (24 °C) would be approximately 24.9 kJ h$^{-1}$. Humidification (100%) of inspired gas at room temperature (24 °C) would reduce heat loss to approximately 12.1 kJ h$^{-1}$ thus supplying (through condensation heat) less than 50% of heat loss. Humidification (100%) of inspired gas at 39 °C would provide approximately 20 kJ h$^{-1}$ (4.5 by increased gas temperature and 15.5 by condensation heat) which is 80% of the theoretical heat loss, approximately 8 kJ h$^{-1}$ (66%) more than humidification at room temperature. Therefore, humidification alone at room temperature would supply approximately 60% of the heat supplied by humidification at 39 °C.

However, the humidifier that was used in our experiment at 24 °C provided 80% relative humidity. In this situation, humidification of inspired gas at room temperature (24 °C) would reduce heat loss to approximately 14.6 kJ h$^{-1}$ thus supplying (through condensation heat) approximately 40% of heat loss or approximately 50% of the heat supplied by 39 °C humidification.

We agree with Dr Lloyd's conclusions; our experiment design did not allow comparison of warm humidification with a true control or with oesophageal warming alone. Our study compared the effect of ventilation with warm (39 °C) humidified (100%) gases, which is the 100% airway warming (AW) in this experiment, with 50% AW and 50% AW with oesophageal warming. A strict "*in vitro*" procedure should have supplied 0% AW during the warm humidification period.

We do not agree with Dr Lloyd's conclusion that our study is invalid. We planned to compare two heating systems in a controlled, standardized clinical condition; ventilation with dry gases does not exist now in clinical practice. Moreover, the gas from the hospital supply system has a relative humidity at room temperature of approximately 40%: this makes it impossible to use dry gas. In any case, by avoiding the use of a cold humidifier in the warm humidification period, we would have compared the effect of 100% AW with 25% AW and with 25% AW plus oesophageal warming.

## Extraction of nitric oxide and nitrogen dioxide using molecular sieve 5A

Sir,—We read with interest the article by Poulton and colleagues[1] demonstrating the efficacy of a molecular sieve in absorbing both nitric oxide and nitrogen dioxide. However, we have some reservations with regard to the clinical applicability of this bench test.

We have recently used a molecular sieve 5A, pellet size 1.5 mm (SW Scientific, Bristol, UK) in a vertically mounted Waters canister (id 6.5 cm, length 10 cm) for the purpose of scavenging nitric oxide and nitrogen dioxide from the expired gas of patients receiving inhaled nitric oxide during mechanical ventilation. However, after using this method in two patients we have failed to demonstrate any efficacy.

Both patients were given inhaled nitric oxide via a Servo 900C ventilator (Siemens Elba AB, Sweden) and humidification of the inspired gas was provided by a heat and moisture exchanger. At each dose of nitric oxide (0, 2, 10, 20 and 0 ppm) both nitric oxide and nitrogen dioxide were measured in the expired gas immediately before and after the Waters canister using a calibrated electrochemical analyser (Micro Medical, Kent, UK). There was no measurable nitrogen dioxide with any dose of nitric oxide (table 1)

As can be readily seen we could not repeat the results of Poulton and colleagues. There are two possible explanations for this. First, we did not heat the zeolite to 400 °C for 24 h as we had been informed this was not necessary for efficacy (personal communication, SW Scientific). Second, the gas flowing through the Waters canister in our case not only contained nitric oxide and oxygen but also nitrogen, carbon dioxide and water. It is likely

*Table 1* Concentration of nitric oxide (NO) delivered to the patient, before molecular sieve 5A and after molecular sieve 5A

| | NO delivered to patient | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | 0 ppm | | 2 ppm | | 10 ppm | | 20 ppm | | 0 ppm | |
| | Patient 1 | Patient 2 | Patient 1 | Patient 2 | Patient 1 | Patient 2 | Patient 1 | Patient 2 | Patient 1 | Patient 2 |
| NO to patient | 0.4 | 0.2 | 2.4 | 2.1 | 10.2 | 10.5 | 19 8 | 20.6 | 0.5 | 0.4 |
| NO before sieve | 0 | 0 | 1.5 | 1.6 | 6.1 | 6.7 | 13 1 | 12.6 | 0 | 0 |
| NO after sieve | 0 | 0 | 1.4 | 1.4 | 5.1 | 5.2 | 12.1 | 11.8 | 0 | 0 |

that nitrogen, carbon dioxide and water alter the performance of the sieve and although this was mentioned by Poulton and colleagues the effect was not quantified. If it is really necessary to dry the zeolite by prolonged exposure to high temperature then the effect of expired water vapour on the function of the sieve may be significant. Further work is necessary to clarify these points.

In conclusion we agree that efficient scavenging of nitric oxide and nitrogen dioxide from a dry carrier gas comprising oxygen only can be achieved using a molecular sieve 5A but we have been unable to reproduce this result in clinical practice. We feel that extrapolation of this bench test result to clinical practice should be undertaken with caution.

Sir,—Thank you for the opportunity to respond to the comments of Findlay, Swart and Smithies relating to the use of molecular sieve 5A as a scavenging device in nitric oxide therapy. We feel that these authors have been misinformed about the crucial importance of dehydrating the sieve before use. As we have outlined in our article, the internal structure of the sieve is charged and therefore intensely hygroscopic; 125 g of dry sieve may be expected to take up 40 g of water. When the internal pores are saturated, the zeolite loses its ability to function as a sieve. Water vapour entering the sieve also reacts with nitric oxide to form nitric acid which leads to degeneration of the sieve. Clearly if our bench top experiment is to be applied clinically, all possible precautions must be taken to exclude water from the sieve. We have already alluded to the possible use of a bed of silica gel. Condensation trapping devices could also be used.

We do not believe that any other technical errors are to blame for the large discrepancy between our own observations and those of Findlay, Swart and Smithies. The sieving capabilities of the zeolite depend on its existence in the dehydrated state.

# BOOK REVIEWS

*Interventional Pain Management.* WALDMAN AND WINNIE (editors). Published by WB Saunders and Co, London. Pp. 582; indexed; illustrated. Price £97.00.

Perhaps the title of this new book does not give justice to its content. The volume is more than an encyclopaedia of practical procedures; it is a comprehensive dissertation on many aspects of chronic pain but with an emphasis on interventional techniques. The editors have assembled contributions from nearly 50 authors, mainly from the USA, and incorporated numerous diagrams and photographs. It consists of six sections: anatomy and physiology of pain, patient evaluation, neural block, neural augmentation, spinal opioids and, finally, neurosurgical techniques.

The first two sections provide useful summaries on the background of pain management A particularly good chapter describes the functional anatomy of the spine. However, the heart of the book is in section 3 where 25 chapters describe various neural blocks. It is clear that the authors of these chapters perform these blocks very regularly as the text is full of practical tips and hints. There are scores of clear radiographs and line diagrams. It is very difficult to find a neural block which is not well described in this section. Although multiple authors have contributed to this section, the chapters follow a set format. Therefore, each block is considered under historical considerations, indications, contraindications, relevant anatomy and practical considerations and complications. The quality of the illustrations cannot be over emphasized

The fourth section considers spinal cord and peripheral nerve stimulation Again, a practical approach to this area is taken but there are also excellent chapters considering the mechanism of action of neural stimulation, selection of patients and problems of the techniques. The fifth section addresses the use of spinal opioids and the first chapter summarizes very nicely the current status of this technique. Again, the emphasis is on practical considerations and the early detection of problems and their management. The final section considers briefly neurosurgical techniques for the management of pain and provides a logical conclusion to the book.

I am sure that all practitioners in chronic pain management will find this book of great practical value. The index of books such as this is very important and I have found it accurate and comprehensive. Although I have emphasized the practical nature of this book, each chapter is supported by numerous references, many very recent.

In summary, this is a significant contribution to the available literature on chronic pain management. If you require a book which comprehensively describes every block you are likely to perform and guides you through procedures step-by-step, then buy this one

*D. Rowbotham*

*Psychology of Pain.* S. SKEVINGTON. Published by John Wiley, Bognor Regis. Pp. 348; indexed. Price £16.99.

It was a privilege and pleasure to be asked to review this excellent textbook. Dr Skevington has offered a penetrating and scholarly analysis of the psychology of pain seen from her particular perspective as a social psychologist. The book therefore differs from other books both in its standpoint and also in much of its content.

The introduction sets the emphasis of the book not only as an articulation of socio-cognitive processes, but as an examination of the social context in which communication occurs about pain. Given the clear limitations of the signs and symptoms based approach of traditional medicine, with its associated iatrogenic incapacity, Skevington's book offers an illuminating slant on the treatment process which is particularly relevant in this new era of "evidence-based" medicine.

Chapter 1 on biological mechanisms, and chapter 2 on measuring painful sensations, while covering much material available elsewhere in the literature, form a clear and helpful background for the initiate.

Chapter 3 on learning about pain offers much more than a traditional "learning-theory" analysis of pain behaviour in terms of stimuli and responses. It offers essentially an analysis of how people become pain patients. Although some of the theoretical background to consultation behaviour may be familiar to the more psychologically oriented, the chapter is well referenced and offers a refreshing update to the field, particularly from the viewpoints of development across time and of the family context.

One of the strongest features of the book is the link between beliefs, images and memories of painful illness (chapter 4); beliefs about control and causation (chapter 5) and "taking the decision" (chapter 6). In chapter 4, the development of beliefs about pain in childhood is linked with an analysis of the social processes involved in the development of identity as a pain sufferer. In this process, the role of memory of pain in shaping pain experience is seen as critical. Beliefs about control and causation affecting pain and illness are outlined in chapter 5. The material and analysis in this chapter will be familiar to most readers. The discussion of PCA is particularly interesting.

It is argued in chapter 6 that although the role of cognitive factors in health care seeking has been well recognized in the literature, the mechanisms of health care seeking (from the psychological point of view) have not been adequately explored. The scholarly description of subjective expected utility (SEU) theory, the health belief model (HBM) and the theory of reasoned action (TRA), while critical to an adequate understanding of the decision-making process, are perhaps a little esoteric for the general pain specialist.

Chapter 7, on the consultation process, is much more "accessible". Analysis of distress, suffering and loss leads to discussion of the nature of communication about pain, which is appraised both from the verbal and non-verbal perspectives. The second part of the chapter of health care seeking and doctor–patient communication is particularly interesting. In addition to a wealth of illuminating general analyses, pain relief in children and the treatment of burns are considered as situations in which emotion has a high profile. The chapter concludes with a consideration of sense of the socio-emotional impediments to successful pain relief.

Chapter 8, on coping with pain, contains much that will be familiar to readers of the journal *Pain.* The chapter serves as a useful source for much of the "coping" literature. Attention is drawn, rightly, to some of the conceptual ambiguities still present in this field. The concluding section on how doctors cope with pain offers an interesting perspective.

An analysis of the social features of treating pain is offered in chapter 9. Written from a fairly holistic perspective, cancer pain specifically is investigated. More specific topics such as treatment adherence and the placebo effect are considered. Both are examined from a social perspective. The chapter concludes with a section on alternative therapy, but in fact considers mainly acupuncture and TENS.

In the final chapter (10), the "way forward" is considered. A number of additional topics such as gender, ethics and social policy are considered. These are described as "broader issues", although there is a suspicion that they are examples of "unfinished business", aspects of which have been dealt with throughout the book The issue of quality of life is also addressed. The book concludes with a model of psychosocial processes and social factors in the form of a helpful figure (pp292–293) which depicts the author's overall framework and represents the breadth of canvas on which the author has decided to paint.

In conclusion, this book is an important contribution to the scientific literature. It should certainly be mandatory reading for all psychologists in the field of pain. It is well referenced and as such, in addition to its intrinsic merit, will serve as an invaluable source. It offers a unique and penetrating guide to the psychosocial processes surrounding pain and its interpretation. While the book does not attempt to appraise, except in passing, the worth of clinical intervention, it is perhaps a pity that more attention was not paid to the social psychology of the modern interdisciplinary pain management programmes currently being developed not only as tertiary treatment facilities, but also in primary care and occupational settings. However, the strengths of the book are considerable, and there is much of value for all professionals in the field of pain.

## EDITORIAL I

### Recovery after major surgery: does the anaesthetic make any difference?

Recovery is a term used frequently in anaesthetic and surgical publications. Many factors may affect recovery, but what does the term imply? Among doctors, nurses and patients the term may be perceived very differently. An anaesthetist may state that recovery has occurred when the patient regains consciousness and physiological stability is present; a surgeon may claim that the patient has recovered when the sutures are removed or when the patient is discharged from hospital. Patients, however, may consider that recovery only ensues when they are able to return to work or have the energy to resume their previous lifestyle. With so many different interpretations, patient recovery becomes extremely difficult to measure.

The variable used most often to assess recovery is duration of hospital stay. It is a reasonable assumption that the patient must have gained some degree of recovery to leave hospital, but this variable is influenced by many factors. For example, the practice of keeping patients in hospital so that they can vacate beds as the next surgical patient arrives, artificially prolongs duration of stay. Despite the absence of accurate data, it is important to consider if modern anaesthetic and surgical practices have hastened recovery after major surgery.

Duration of hospital stay has been declining over the past four decades, not only in the National Health Service (NHS), but also in the private sector.[1] Patients undergoing hysterectomy in the NHS between 1948 and 1957 stayed in hospital for 21 days, but this had decreased to 10 days by 1978–1983. This trend has also been noted in the USA, in spite of an increase in the complexity of medical problems associated with surgery.[2] Duration of stay continues to decrease, and in our hospital in London in 1996, patients undergoing hysterectomy stayed for only 4–5 days. Two key facets of anaesthesia may be implicated; attenuation of the neuroendocrine response to surgery and improved analgesic regimens.

Following Kehlet's suggestion that neuroendocrine changes are not essential and obtunding them may improve surgical outcome, extradural analgesia and anaesthesia have been used extensively to decrease the stress response to surgery. Occasional reports have found beneficial effects on morbidity, and even mortality,[3–5] but two comprehensive reviews in 1988 and 1995 found only limited improvements in selected surgical procedures.[6,7] Indeed, Liu, Carpenter and Neal concluded that more studies are needed to determine if a relationship exists between the stress response and postoperative morbidity.[7] Few investigators have examined the problem directly and most data are derived from studies in which recovery was not a primary end-point. Liu, Carpenter and Neal also argue for more and better variables to assess recovery, such as return to work.

An improvement in postoperative analgesia has become the major thrust of many anaesthetic departments in recent years. Patient-controlled analgesia (PCA) has been adopted enthusiastically and there have been many studies promoting its advantages over conventional analgesic regimens. Although there were a few early reports indicating a more rapid discharge from hospital with PCA, meta-analysis of initial, randomized, control studies found no significant improvement.[8] Mean duration of hospital stay was only 0.15 days shorter with PCA compared with conventional regimens. Neural block provides excellent postoperative pain relief, but again has little impact on recovery. Two studies using extradural analgesia after orthopaedic and colonic surgery failed to show a decrease in the duration of hospital stay.[9,10] The effects of different extradural analgesic regimens on recovery after colonic surgery were reported recently.[11] Extradural bupivacaine and extradural bupivacaine–morphine provided better analgesia than extradural morphine or morphine PCA, and were associated with more rapid recovery of gastrointestinal function. However, duration of hospital stay was similar in all groups, although the time to fulfil predetermined discharge criteria was improved significantly in patients who received extradural bupivacaine or extradural bupivacaine–morphine. The authors emphasized that, despite prospective agreement with all surgeons, and education of patients, nurses and residents, some patients were not discharged on meeting the fixed criteria. Reasons included travel arrangements, social situations and the patient's or surgeon's belief that further observation in hospital was necessary. This study encapsulates the difficulties in trying to examine the effects of anaesthetic techniques on recovery.

It seems likely that anaesthesia has only a minor role to play in enhancing recovery. Changes in surgical technique and the introduction of laparoscopic procedures have been more productive. There is general agreement that duration of hospital stay is much less when cholecystectomy is conducted laparoscopically than by laparotomy.[12,13] Similar benefits have been claimed for appendicectomy,[14] and laparoscopic hernia repair was associated with more rapid return to work.[15] The consensus on the benefits of laparoscopic cholecystectomy was challenged in 1996 when a laparoscopic technique was compared with small-incision laparotomy[16]; there was no difference in duration of hospital stay, time back to full employment and time taken to return to full activity. This study used a novel method of determining recovery; the patient decided when to leave hospital. It is of interest that the duration of stay was 3 days with both techniques, possibly longer than anticipated after laparoscopy and shorter than expected after mini-laparotomy.

Nevertheless, the use of laparoscopic techniques is associated with rapid recovery and early discharge. The classical neuroendocrine response to abdominal surgery is similar with both techniques, but there is a significant decrease in markers of the inflammatory response to tissue damage, such as interleukin-6 and C-reactive protein with laparoscopy.[17 18] The concept that tissue damage is a key determinant of recovery is supported by studies in which the length of the abdominal incision was varied[19] and the use of even smaller laparoscopic ports.[20]

Bardram and colleagues combined recent developments in surgical and anaesthetic practice to enhance recovery in nine elderly patients undergoing colonic surgery.[21] The surgery was laparoscopically assisted and this was combined with extradural analgesia with bupivacaine, early oral feeding and rapid mobilization. Opioids were avoided, if possible, and used only for rescue analgesia. Hospital stay was decreased to 2–3 days compared with the usual 8–10 days. These results are extremely impressive and show what can be achieved by enthusiastic anaesthetic and surgical collaboration. It is not possible from the design of the study to identify those factors responsible for the improvement. Further work with larger numbers of patients and suitable control groups will permit the relative contributions of anaesthetic and surgical factors to be determined.

At present we anticipate that patients who undergo major surgery will stay in hospital for up to 10 days. These expectations are known widely in the community and in hospital. Majeed and colleagues found it necessary to blind the nursing staff and the patient to the type of surgery (laparoscopy or mini-laparotomy for cholecystectomy).[16] This was achieved by randomizing patients after they had been anaesthetized, restricting nursing access to the operative details and by placing identical blood stained dressings on the patients. The dressings were not removed until the patient decided that they were fit for discharge. The investigators also wrote to the general practitioners asking them not to influence the time taken by the patient before returning to work. The care taken to try to eliminate bias in this study shows how entrenched the expectations of patients, doctors and nursing staff are over recovery from major surgery. Cultural factors may be as important as anaesthetic and surgical techniques in influencing recovery.

Research into recovery after surgery is important for information, planning and economic reasons. A clear definition of recovery must be found together with an effective method of measuring this variable. We have discussed briefly some of the problems associated with using duration of stay to assess recovery. The patient's view of recovery must be taken into account and not just those areas of interest to medical staff (resumption of oral intake, days of analgesic therapy, etc). This requires research projects to be extended into the period of convalescence after the patient has left hospital. This critical time has largely been ignored, so far, and yet is of major importance to the patient.

# EDITORIAL II

## Low-dose dopamine: will there ever be a scientific rationale?

Perioperative renal dysfunction is a well recognized complication in patients undergoing elective repair of abdominal aortic aneurysm (AAA). Postulated mechanisms include diminished preoperative renal function, tubular functional impairment secondary to altered intrarenal circulation, activation of the renin–angiotensin–aldosterone system, reduced distal tubular sodium delivery and atheromatous emboli.[1 2] Infrarenal aortic cross-clamping *per se* has been demonstrated to produce profound and sustained alterations in renal haemodynamics (38% reduction in renal blood flow and 75% increase in renal vascular resistance) in the absence of significant changes in cardiac output or systemic vascular resistance.[3] Prolonged aortic cross-clamping, hypotension and large-volume blood transfusion are important risk factors in the development of postoperative renal impairment in this patient population.[4] Acute renal failure (ARF) in this context carries a high mortality rate, and its avoidance is an important goal of postoperative management.[5] Hence, the findings of Girbes and colleagues[6] in a recent issue of *British Journal of Anaesthesia* that an infusion of dopamine 2–4 $\mu g\ kg^{-1}\ min^{-1}$ increased glomerular filtration rate (GFR) and renal blood flow (RBF) in seven haemodynamically stable patients undergoing mechanical ventilation and receiving postoperative extradural analgesia after elective AAA repair merits attention and critical analysis. The authors attributed the dopamine-induced increased GFR and RBF to increased cardiac output and they went on to conclude that "if an increase in RBF and GFR is considered as a goal of treatment, our data indicate that 4 $\mu g\ kg^{-1}$ is the optimal dose of the given doses".

Do the findings of this study support the claims often made by proponents of "renal-dose" or "low-dose" dopamine that such a regimen augments RBF, GFR and/or natriuresis in healthy humans and experimental animals, and limits adenosine triphosphate utilization and oxygen requirements in nephron segments at risk for ischaemic injury, actions that could potentially limit renal injury and accelerate recovery in ARF?. Undoubtedly, dopamine infusion induces a dose-dependent increase in RBF, natriuresis and diuresis in healthy experimental animals and humans[7] and improves RBF in patients with chronic renal impairment, renovascular disease and mild to moderate sodium depletion.[8] The mechanisms by which dopamine modulates RBF differ depending on the rate of infusion.[9] At low doses (threshold 0.5, maximum 3.0 $\mu g\ kg^{-1}\ min^{-1}$), dopamine augments RBF principally by DA1 receptor-induced intrarenal vasodilatation and possible contributory engagement of DA2 receptors on presynaptic sympathetic nerve terminals with inhibition of noradrenaline release. Intermediate doses of dopamine (threshold 3.0, maximum 10 $\mu g\ kg^{-1}\ min^{-1}$) are thought to augment renal perfusion by increasing cardiac index via cardiac $\beta_1$-adrenoreceptor stimulation. Higher doses of dopamine administration (threshold 5.0, maximum 20 $\mu g\ kg^{-1}\ min^{-1}$) may produce systemic vasoconstriction via $\alpha$- adrenoceptor stimulation.

An important caveat worthy of note is that the above-mentioned dopamine dose–response relationships were advanced after studies in normovolaemic healthy subjects. Do they apply to the potentially hypovolaemic and hypothermic patient, with coexisting ischaemic heart disease, hypertension or diabetes in the immediate postoperative period? In this uncontrolled, small scale study of relatively normovolaemic, normothermic patients without coexisting cardiac or renal impairment, infusion of dopamine 2–4 $\mu g\ kg^{-1}\ min^{-1}$ increased urine output, GFR and RBF. What was/were the mechanism(s) involved?. The mechanisms by which dopamine exerts its renal effects are complex and might include: $\beta$-adrenoceptor-mediated increase in cardiac output; DA1 and DA2 receptor-mediated vasodilatation and increased RBF; increased delivery of diuretics to the distal tubule; decreased renin–angiotensin–aldosterone activation; or direct effects on tubular function.[10] Increased cardiac output and RBF were the most striking findings in the study by Girbes and colleagues.[6] Plasma renin activity was essentially unchanged, while plasma aldosterone concentrations were reduced significantly when an infusion of dopamine 8 $\mu g\ kg^{-1}\ min^{-1}$ was given. Dick, Dasta and Choban, in a study of oliguric, critically ill surgical patients, reported that an infusion of dopamine 2–5 $\mu g\ kg^{-1}\ min^{-1}$ for 6 h decreased serum aldosterone concentration with increased urine output and sodium excretion.[11]

Do the results of this study suggest a role for prophylactic low-dose dopamine in this clinical context? The authors make no such claim based on their observations. Moreover, several recent editorials have strenuously urged abandonment of low-dose dopamine therapy in the treatment of ARF.[10 12] Paul and colleagues observed no clinically important benefit from intraoperative administration of mannitol and dopamine compared with extracellular fluid volume expansion with saline alone in the prevention of changes in renal function associated with aortic cross-clamping.[13] Studies assessing the efficacy of "renal" or low-dose dopamine in the prevention of ARF in high-risk clinical situations—major cardiac surgery, vascular or biliary surgery, renal and liver transplantation, and exposure to contrast material—have been challenged on the basis of patient numbers and study methods. In a prospective, randomized controlled study of 37 patients undergoing elective abdominal aortic surgery, 24-h infusion of dopamine 3 $\mu g\ kg^{-1}\ min^{-1}$ in the postoperative period did not improve creatinine clearance or reduce serum creatinine concentrations measured after 1 and 5 days, respectively.[14] Two postoperative deaths occurred in the dopamine group (from renal failure and myocardial infarction). Four patients had myocardial infarction, three of whom received dopamine.

In examining the potential therapeutic effects of low-dose dopamine, it is necessary to perform a risk–benefit analysis regarding deleterious side effects.[15] This process is essential when the treatment is of questionable benefit. Girbes and colleagues[6] reported no major changes in heart rate in the seven patients studied. None the less, dopamine is a potent catecholamine, with positive inotropic and chronotropic activity, even in the low doses used in the study. Apart from the obvious potential problems with tachycardia and increased myocardial oxygen consumption, dopamine may depress hypoxic respiratory drive[10] and, in a porcine shock model, was reported to divert blood flow away from the gut mucosa.[16] Administration of dopamine warrants central venous cannulation, and drug extravasation adjacent to an artery may provoke distal ischaemia and gangrene.[17]

There is no doubt that dopamine in low doses in healthy kidneys leads to an increase in urine output, accompanied by natriuresis and kaliuresis. Low-dose dopamine, as used by Girebes and colleagues,[6] appeared to function as a "diuretic" with perhaps some inotropic and renal vasodilator properties. This diuresis would be a dubious blessing if it were to mask or even cause hypovolaemia and subsequent renal hypoperfusion. The absence of prospective, controlled, large-scale studies confirming reduced incidence of ARF and improved outcome three decades after the first reports of administration of renal protective doses of dopamine remains a concern. Perhaps clinicians and investigators should focus attention on catecholamines such as dobutamine, devoid of diuretic properties, but with the potential to augment cardiac output and renal blood flow?

CLINICAL INVESTIGATIONS

# Effect of an upper respiratory tract infection on upper airway reactivity

N. NANDWANI, J. H. RAPHAEL AND J. A. LANGTON

## Summary

Patients presenting for elective anaesthesia and surgery may be suffering with, or recovering from, a recent upper respiratory tract infection (URTI). It is a frequent clinical problem as to whether to postpone surgery in such patients as they may be more likely to suffer adverse respiratory events related to administration of general anaesthesia. Using dilute ammonia vapour as a chemical stimulus, we measured upper airway reactivity in 11 healthy volunteers (six males), mean age 39.8 (range 30–58) yr, who had symptoms of an URTI. Volunteers were recruited 24–72 h after symptoms first began, and followed-up at regular intervals for the next 8 weeks. Measurements of upper airway reactivity were made on the following days (±24 h) after commencement of URTI symptoms: 3, 6, 9, 15, 20 and 27. Additional measurements were obtained 56 days after symptoms first began, and these were regarded as baseline measurements. Upper airway reactivity was increased on days 3, 6 and 9 compared with baseline measurements ($P<0.01$, Wilcoxon). There was no significant change in airway reactivity from day 15 onwards, by which time 10 of the 11 subjects were completely devoid of symptoms. All subjects were asymptomatic by day 20 and remained so until the study ended on day 56. We conclude that upper airway reactivity was increased during the acute phase of an URTI, and that this appeared to be related to the presence of symptoms. (*Br. J. Anaesth.* 1997; **78**: 352–355).

**Key words**
Airway, reflexes. Infection, respiratory tract. Complications, respiratory. Complications, infection.

Most adults suffer at least one upper respiratory tract infection (URTI) per year. The incidence increases to 5–6 episodes per year in children. Therefore, many patients presenting for elective surgery and anaesthesia may either be suffering with, or recovering from, a recent URTI.

The decision whether or not to anaesthetize such a patient is a common clinical dilemma. In the past it has been routine practice to postpone anaesthesia and surgery in patients suffering from an URTI, but this may have medical, social and financial consequences. There have been relatively few studies investigating this important clinical area and these have focused on the incidence of adverse respiratory events associated with anaesthesia in children. In a large prospective study, Cohen and Cameron studied 1283 children with symptoms of an URTI and 20 876 children without any symptoms who were undergoing elective surgery.[1] They found that children suffering from an URTI were three times more likely to suffer an adverse respiratory event; the risk increased 11-fold if tracheal intubation was performed. In 1992, Levy and colleagues[2] found that children with an acute or recent URTI had an increased likelihood of transient hypoxaemia in the perioperative period. There has also been a well documented case report of laryngospasm resulting in death in a child recovering from a recent URTI.[3] It has even been suggested that an anaesthetist may be negligent for anaesthetizing a child while suffering from an URTI.[4]

At present there are few studies which have investigated adult patients with symptoms of an URTI undergoing anaesthesia. There is however evidence of increased bronchial reactivity in adults suffering from an URTI; Empey and co-workers demonstrated a 200% increase in airway resistance in response to inhaled histamine in subjects with colds compared with a 30% increase in controls.[5] There is however little evidence to demonstrate that anaesthesia in adult patients with an URTI leads to an increased incidence of respiratory complications.

We are able to measure upper airway reactivity in subjects by using dilute ammonia vapour as a chemical stimulus to the upper airway.[6] The aim of this study was to determine the sensitivity of upper airway reflexes during an URTI and to record the duration of any possible changes and the relationship of these changes to the presence of symptoms.

## Subjects and methods

After obtaining Ethics Committee approval and written informed consent, we studied 12 volunteers,

*Present address: Derriford Hospital, Plymouth, Devon PL6 8DH.

Correspondence to N. N.

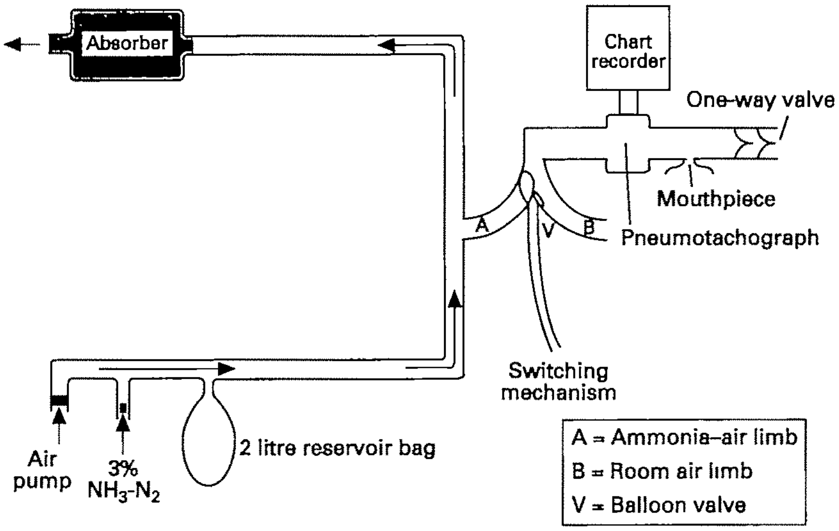

*Figure 1* Schematic diagram of the equipment used to measure upper airway reactivity.

24–72 h after symptoms of an URTI first began. All volunteers were non-smokers and not receiving any medication. Exclusion criteria included a history of asthma or an URTI in the previous 3 months.

URTI was defined according to similar criteria as used by Tait and Knight.[7] Symptoms were divided into three categories: nasal—discharge, obstruction, sneeze; throat—sore throat, non-productive cough; systemic—malaise, muscular ache, temperature less than 38 °C.

Subjects were recruited into the study if they had at least one symptom from each category and were deemed to be asymptomatic only when all symptoms had completely disappeared. Subjects were not studied if they had a temperature greater than 38 °C, productive cough or evidence of lower respiratory tract infection.

All subjects were followed-up at regular intervals over the next 8 weeks. Measurements of upper airway reactivity were made on the following days (±24 h) after commencement of URTI symptoms: 3, 6, 9, 15, 20 and 27. Additional measurements were obtained 56 days after symptoms first began and these were regarded as baseline measurements. The presence or absence of symptoms was also recorded.

Upper airway reflex sensitivity was measured using a previously described method which uses low concentrations of ammonia vapour as an irritant chemical stimulus to the upper airway during inspiration.[6] Briefly, the subject was asked to breathe through a close-fitting mouthpiece while wearing a noseclip and to exhale to atmosphere via a one-way valve (fig. 1). The mouthpiece was attached to a pneumotachograph which records airflow onto a chart recorder. A pneumatic two-way balloon valve was situated between limbs A and B of the breathing circuit. This balloon valve allowed the investigator to switch rapidly between room air and dilute ammonia vapour. Subjects wore dark goggles and listened to music through headphones so that they were unaware of the switching of the pneumatic valve.

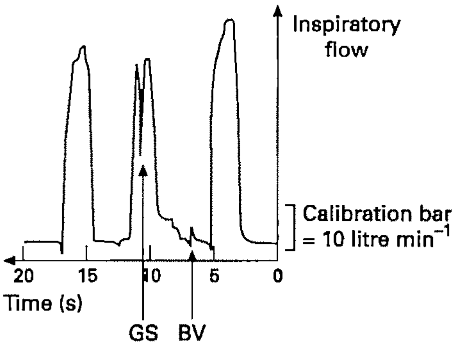

*Figure 2* Example of a glottic stop recording. GS=Glottic stop, BV=switching of the balloon valve, allowing the subject to take a single breath from the ammonia–air limb.

In this way the subject's upper airway was exposed to single intermittent breaths containing small concentrations of ammonia vapour and the threshold concentration ($NH_3TR$) required to elicit glottic closure was recorded. We defined glottic closure as a rapid decrease in inspiratory flow, the flow decreasing by at least 25% of peak inspiratory flow, followed by a swift recovery, and the whole event lasting less than 0.5 s (fig. 2). Low values for $NH_3TR$ are associated with increased sensitivity of the upper airway, high values represent depression of upper airway reflex sensitivity.

Ammonia was supplied via a Rotameter from a 3% ammonia–nitrogen cylinder supplied by the British Oxygen Company. This was added to room air 10 litre $min^{-1}$ to deliver accurate concentrations of ammonia vapour in the range 0–3500 ppm. Calibration of the system has been described previously.[6] By altering the flowmeter settings by increments of 50 ml $min^{-1}$, corresponding to mean (range) changes in ammonia concentration of 171 (125–235) ppm, we were able to determine the minimum concentration of ammonia vapour required to elicit glottic closure ($NH_3TR$).

## Results

Eleven subjects (six males), mean age 39.8 (range 30–58) yr, completed the study. One subject was completely devoid of symptoms by day 6, five by day

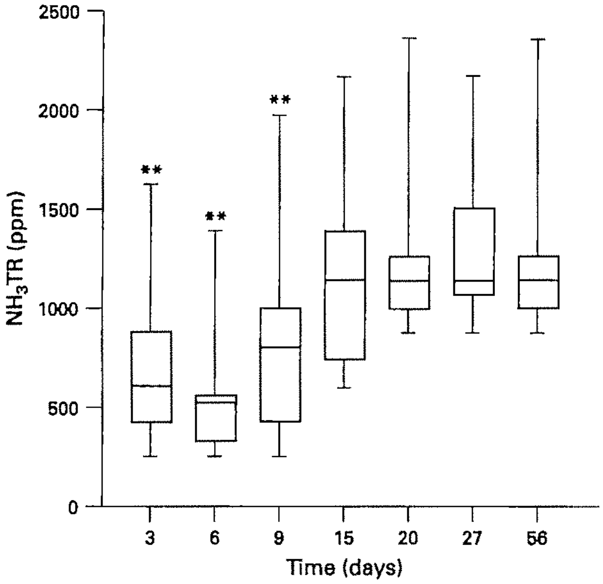

*Figure 3* Ammonia threshold concentration ($NH_3TR$) in volunteers with an upper respiratory tract infection (URTI) showing the median, interquartile range and 10th and 90th percentiles. **$P<0.01$ (Wilcoxon).

9 and 10 by day 15. All were asymptomatic by day 20 and remained so until the study ended on day 56 when the baseline $NH_3TR$ measurements were recorded.

There was a decrease in $NH_3TR$, corresponding to an increase in upper airway reactivity, from a baseline mean of 1255 (SEM 126) ppm to 674 ppm (116) on day 3, 587 ppm (108) on day 6 and to 806 ppm (170) on day 9 after the commencement of URTI symptoms (fig. 3). Using Friedman two-way ANOVA and Wilcoxon matched pairs signed ranks test, these changes were statistically significant ($P<0.01$).There was no significant change in $NH_3TR$ compared with baseline measurements from day 15 onwards.

## Discussion

Upper airway reflex activity is important to the anaesthetist because it is involved in both airway protection and upper airway complications such as cough and laryngospasm. We are able to measure upper airway reactivity using small concentrations of ammonia vapour as a chemical stimulus to the upper airway.[6] Using this technique previous studies have shown that airway reflexes are depressed by administration of oral benzodiazepines[8] and also by topical administration of lignocaine to the vocal cords.[9] It has also been shown that upper airway reactivity decreases with advancing age.[10] In comparison, chronic smokers have significantly greater airway reactivity than non-smokers,[11] an effect that can last for up to 10 days after abstinence from cigarettes.

The exact mechanism responsible for reflex glottic closure has not been fully elucidated. Receptors known to respond to chemical irritants are found in the epithelial and subepithelial layers of the pharynx and larynx. Afferents from these receptors travel mainly in the superior laryngeal nerve and synapse in the brain stem. In adult humans the main response to irritant receptor stimulation is glottic closure and a brief pause in inspiration. Higher concentrations of irritants result in cough. We have used the threshold concentration of dilute ammonia vapour required to elicit glottic closure ($NH_3TR$) as a measure of upper airway reactivity.

It is thought that the epithelial lining of the upper airway plays an important role in restricting access of inhaled irritants to the subepithelial receptors. It is known that infection of the upper respiratory tract results in mucosal oedema followed by shedding of the epithelial cell layers.[12] Loss of airway epithelium can extend down to the basement membrane and may persist for as long as 3 weeks after the initial infection. Our findings of increased upper airway reactivity during the acute phase of an URTI agree with the findings of Empey and colleagues, who demonstrated that bronchial reactivity in response to inhaled histamine is increased during an URTI.[5] Chronic smokers also develop inflammation and destruction of the protective epithelial barrier[13] and this may account for the increase in upper airway reactivity which has been demonstrated previously.[11]

The diagnosis of URTI is complicated by the fact that a particular clinical syndrome is not always associated with a specific pathogen. The rhinovirus, myxovirus and respiratory syncytial virus are the most common pathogens. We recruited subjects on the basis of the presence of symptoms attributable to an acute URTI.[7] We did not attempt to perform viral cultures as this would have been neither practical nor cost-effective for a self-limiting usually benign condition. In everyday anaesthetic practice the presence of symptoms would be used to assess the need to postpone surgery.

There is some interest in the effect of inhaled anaesthetic agents on the course of an URTI. It has been suggested that after surgery and anaesthesia there may be a decrease in both the severity and duration of certain respiratory symptoms. Tait and Knight[7] found a significantly lower incidence of sore throat, sneezing, malaise and fever in children after general anaesthesia compared with those that were not. Earlier *in vitro* studies examining exposure of several viruses to halothane demonstrated dose-dependant inhibition of viral replication.[14] This effect is thought to result in part from a decrease in synthesis of viral proteins, although these *in vitro* experiments required an exposure time equal to the replicative time of the virus. Nevertheless these studies demonstrate the sensitivity of some viruses to anaesthetic agents which could potentially be reflected in the clinical situation. These findings are of special interest as they add an additional clinical perspective.

An editorial in the *British Journal of Anaesthesia* in 1990[15] highlighted the fact that to date there is little evidence to show that general anaesthesia administered to an adult patient with an URTI results in an increased incidence of adverse respiratory events. Our study has demonstrated that upper airway reactivity was increased during the acute phase of an URTI. In addition, we have shown that this increase appeared to be related to the presence of symptoms. However, the exact relationship between an increase in the sensitivity of airway reflexes and the incidence of upper airway problems requires further investigation.

# Inhalation induction with sevoflurane: a double-blind comparison with propofol†

A. THWAITES, S. EDMENDS AND I. SMITH

## Summary

We conducted a randomized, double-blind comparison of 8% sevoflurane and propofol as induction agents for day-case cystoscopy in 102 patients. All patients received an i.v. cannula and breathed oxygen 5 litre min$^{-1}$. Anaesthesia was induced with propofol i.v. or inhalation of 8% sevoflurane and 10% Intralipid (as a placebo) i.v., delivered by a blinded observer. Anaesthesia was maintained in all patients with 2% sevoflurane via a face mask. Induction of anaesthesia with sevoflurane was significantly slower compared with propofol (mean 84 (SD 24) s *vs* 57 (11) s), but was associated with a lower incidence of apnoea (16% *vs* 65%) and a shorter time to establish spontaneous ventilation (94 (34) s *vs* 126 (79) s). Induction complications were uncommon in each group but the transition to maintenance was smoother with sevoflurane and was associated with less hypotension compared with propofol. Emergence from anaesthesia induced with sevoflurane occurred significantly earlier compared with propofol (5.2 (2.2) min *vs* 7.0 (3.2) min) and anaesthetic induction was also significantly cheaper with sevoflurane. According to a postoperative questionnaire, the majority of patients found both anaesthetic techniques acceptable. Nevertheless, significantly more patients (14%) rated induction with sevoflurane as unpleasant compared with propofol (0) and significantly more patients (24%) would not choose sevoflurane induction compared with propofol (6%). This phenomenon may have been related to the particular patient population studied, however. Inhalation induction with 8% sevoflurane would appear to offer several objective advantages compared with induction with propofol in day-case patients, although a significant minority may dislike this technique. (*Br. J. Anaesth.* 1997; **78**: 356–361).

**Key words**
Anaesthetics volatile, sevoflurane. Anaesthetics i.v., propofol. Anaesthesia, day case. Anaesthetic techniques, induction.

One of the major objections to performing inhalation induction of anaesthesia is patients' dislike of a black rubber face mask. Nevertheless, the widespread availability of modern clear plastic masks, combined with an increasing tendency to use face masks to perform "preoxygenation" before induction of anaesthesia have largely overcome this objection. With the availability of a non-pungent and rapidly acting volatile anaesthetic, it would seem logical to use a face mask both to provide oxygen and induce anaesthesia, thereby avoiding many of the problems associated with i.v. induction.

Sevoflurane has a low blood:gas solubility coefficient (0.69)[1] and is the least respiratory irritant of the available volatile anaesthetics.[2] These properties make sevoflurane an ideal inhalation induction agent.[3] Previous investigations have shown sevoflurane to be an acceptable induction agent in adult patients.[4 5] However, these investigators used an earlier sevoflurane vaporizer which was limited to a maximum output of 5% (compared with 8% on current models). In addition, patients were pretreated with opioid analgesics. Finally, the earlier comparisons were not blinded and did not specifically examine the patient's experience of induction. We therefore conducted a randomized, double-blind comparison of induction of anaesthesia in unpremedicated patients with 8% sevoflurane or propofol (the most commonly used induction agent).

## Patients and methods

We studied 102 ASA I–III patients undergoing day-case cystoscopy for follow-up of bladder carcinoma, haematuria or urinary tract infection, according to a design approved by the Ethics Committee of the North Staffordshire Hospital. After obtaining written, informed consent, patients were allocated randomly to one of two induction groups using computer-generated random numbers and sequentially numbered sealed envelopes. All patients were unpremedicated. Patients with a previous history of malignant hyperthermia or adverse reaction to inhalation anaesthetics or propofol were excluded. Patients receiving sedative medications chronically

†Presented in part at the American Society of Anesthesiologists Annual Meeting, October 1996.

and those with serious, life-threatening respiratory or cardiovascular diseases were also excluded.

Before induction of anaesthesia, one anaesthetist (A. T.) prepared a 20-ml syringe containing either propofol or 10% Intralipid as a placebo control. A 20-gauge i.v. cannula was inserted into the patient's non-dominant hand and 2 ml of 1% lignocaine were administered to all patients. Although lignocaine was injected as prophylaxis against pain on injection of propofol, it was administered to both groups of patients because of possible effects on haemodynamic variables. All patients received oxygen for 1 min from a clear plastic face mask at a flow rate of 5 litre $min^{-1}$ and patients were given a weighted object to hold.[6] At the start of induction of anaesthesia, fresh gas flow was changed to nitrous oxide 4 litre $min^{-1}$ and oxygen 2 litre $min^{-1}$ in all patients. In the sevoflurane group, the non-blinded anaesthetist (A. T.) turned the sevoflurane vaporizer to 8% at the start of induction. A similar hand movement was made in the propofol group, but the vaporizer dial was not actually turned. The sevoflurane vaporizer was hidden from view of the blinded observer (I. S.) by an opaque curtain. Simultaneous with the start of induction, the observer began to inject the contents of the 20-ml syringe (propofol or placebo) at a constant rate of 16–18 ml $min^{-1}$ and continued until the patient dropped the weighted object. Spontaneous patient activities and comments were recorded by the observer. Arterial pressure, heart rate and haemoglobin oxygen saturation ($Sp_{O_2}$) were recorded at 1-min intervals during induction. The observer judged anaesthesia to be induced when the patient dropped the weighted object. At this point, the volume of i.v. drug injected was recorded and anaesthesia was maintained with 2% sevoflurane in both groups of patients, subsequently adjusted up or down as necessary in order to maintain adequate anaesthesia as judged by the usual clinical signs.[7] Anaesthesia was maintained using a face mask. The observer recorded a guess as to which induction agent had been used, evaluated the occurrence of apnoea and recorded when spontaneous ventilation resumed. The occurrence of movements and coughing during the transition period from induction to maintenance was also recorded. All induction sequence events were timed using a palm top computer (Psion, London) and custom software. Oxygen and anaesthesia were delivered using a Humphrey ADE circuit used in its "A" setting. The system was flushed with oxygen 50 litre $min^{-1}$ between patients until the investigators were unable to smell residual sevoflurane.

The costs of induction (see appendix) were calculated on the current list price of the primary induction drug. Induction costs for sevoflurane were based on the list price of the anaesthetic liquid, the volume of vapour produced per ml of liquid (182.7 ml),[8] fresh gas flow and induction time. At the end of the procedure, sevoflurane and nitrous oxide were discontinued simultaneously and the time at which patients opened their eyes to command was recorded by the observer. Before discharge from the day-case unit, patients completed a questionnaire to evaluate their induction experience. Patients were asked about their recollection of the face mask, smells and tastes during induction of anaesthesia and whether or not these were unpleasant. Patients were also asked about pain on injection of the i.v. drug and were asked to guess if their anaesthesia had been induced by "an injection" or by "breathing a gas". Induction of anaesthesia was rated as "pleasant", "neither pleasant nor unpleasant" or "unpleasant". Finally, the patient's willingness to receive an identical anaesthetic induction in the future was determined.

Data were analysed using the Statview statistical package. Continuous variables were analysed using non-paired *t* tests. Discrete data were analysed using chi-square tests or Fisher's exact test as appropriate. Data which were not distributed normally were analysed using an appropriate non-parametric test. In all cases $P<0.05$ was considered significant.

## Results

The two induction groups were comparable in patient characteristics (table 1). Induction of anaesthesia with propofol was significantly more rapid compared with 8% sevoflurane (mean 57 (SD 11) s *vs* 84 (24) s, $P<0.01$). Induction of anaesthesia with propofol required an average of 167 (31) mg (2.3 (0.5) mg $kg^{-1}$). Six patients spoke with slurred speech during induction with propofol compared with seven who received sevoflurane. Purposeful movements were made by three patients in the propofol group and by five in the sevoflurane group ($P=0.46$). In addition, one patient in the sevoflurane group exhibited mild coughing. The induction sequences were sufficiently similar that the observer could identify the induction technique correctly only 65% of the time with propofol and 61% of the time with sevoflurane. Apnoea occurred significantly more frequently in the propofol induction group (33 (65%)) compared with the sevoflurane group (eight (16%)) ($P<0.01$). As a consequence, the time from beginning induction until patients were breathing spontaneously with a regular ventilatory pattern was significantly shorter with sevoflurane compared with propofol (94 (34) s *vs* 126 (79) s, respectively). Coughing after induction of anaesthesia, during the transition to the maintenance phase, occurred in four patients (8%) in the sevoflurane group and in 12 patients (24%) in the propofol group ($P=0.03$).

Mean arterial pressure (MAP) recorded immediately before induction of anaesthesia did not differ significantly between the two groups (fig. 1).

*Table 1* Patient characteristics in the two anaesthetic induction groups. Values are mean (SD or range) or number of occurrences

| | Propofol | Sevoflurane |
|---|---|---|
| Number (*n*) | 51 | 51 |
| Age (yr) | 58 (20–81) | 60 (18–85) |
| Weight (kg) | 73 (14) | 73 (13) |
| ASA (I/II/III) | 18/32/1 | 23/26/2 |
| Sex (M/F) | 29/22 | 31/20 |
| Smoking history | | |
| Non-smoker | 24 | 23 |
| Ex-smoker | 13 | 13 |
| Current smoker | 14 | 15 |

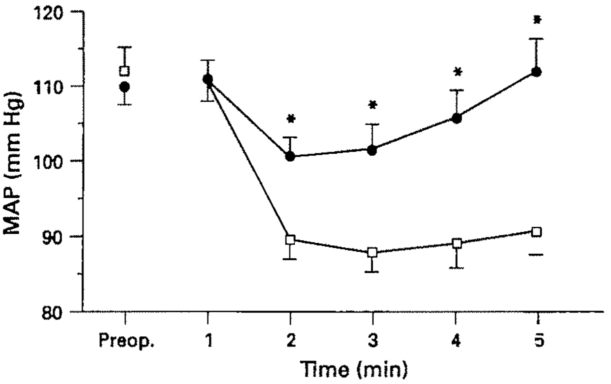

*Figure 1* Mean arterial pressure (MAP) before induction of anaesthesia (Preop.) and at the indicated times after induction of anaesthesia with propofol (□) or 8% sevoflurane (●). Values are mean, SEM. $^*P<0.05$ compared with propofol.

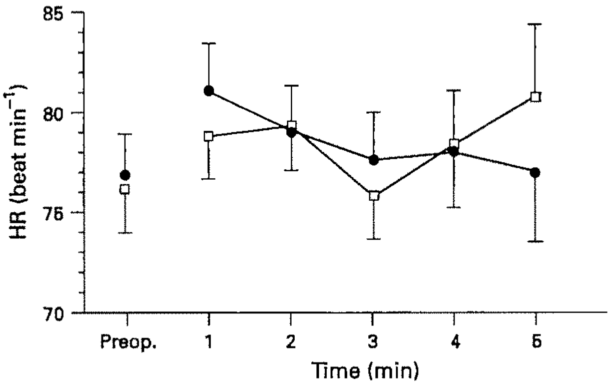

*Figure 2* Heart rate (HR) before induction of anaesthesia (Preop.) and at the indicated times after induction of anaesthesia with propofol (□) or 8% sevoflurane (●). Values are mean, SEM.

Induction of anaesthesia with propofol was associated with a decrease of approximately 20 mm Hg in MAP which occurred within 2 min and persisted for at least the first 5 min of anaesthesia. In contrast, the decrease in MAP with sevoflurane was only 10 mm Hg and MAP had returned to baseline values within 5 min. As a consequence, MAP was significantly lower at 2–5 min after induction of anaesthesia with propofol compared with sevoflurane (fig. 1). Heart rate (HR) increased slightly compared with baseline after induction of anaesthesia with each agent. However, HR did not differ significantly between the groups at any time during induction (fig. 2). There was also no difference in $Sp_{O_2}$ between the two groups at any time.

Patient responses to the postoperative questionnaire are shown in table 2. Most patients recalled the presence of the face mask. While this was well tolerated by the majority of patients, significantly more patients in the sevoflurane group found the face mask unpleasant. Although a smell was reported most commonly by patients receiving sevoflurane (92%), 61% of patients recalled a smell in the propofol group. However, this smell was reported as "unpleasant" by significantly more patients in the sevoflurane group. A taste was also reported more commonly with sevoflurane, although there was no significant difference in the number of patients who described this as unpleasant. When patients attempted to guess which induction technique they had received, they were more inclined to choose the inhalation technique. As a result, significantly more patients guessed correctly in the sevoflurane induction group and incorrectly in the propofol induction group. Induction with propofol was rated as "pleasant" significantly more frequently compared with sevoflurane, with most of the remaining patients either having no recall of induction or providing an indifferent response (neither pleasant nor unpleasant). Induction was described as "unpleasant" by a minority of patients (seven (14%)) all of whom were in the sevoflurane group. There was a tendency for more patients receiving propofol to favour the same induction technique in the future, although this difference was not statistically significant. However, significantly more patients who received sevoflurane (24% *vs* 6%) were unwilling to receive the same induction again ($P=0.02$).

*Table 2* Patient's perspective on induction of anaesthesia. Values are number (%) of responses. $^*P<0.05$ compared with propofol

| | Propofol | Sevoflurane |
|---|---|---|

| Correct | 8 (16%) | 34 (67%)* |
| Incorrect | 21 (41%) | 2 (4%)* |
| No guess attempted | 22 (43%) | 15 (29%) |
| Induction | | |
| Pleasant | 35 (69%) | 24 (47%)* |
| Indifferent | 13 (25%) | 16 (31%) |
| Unpleasant | 0 | 7 (14%)* |
| No recall | 3 (6%) | 4 (8%) |
| Future preference | | |
| Same technique | 31 (61%) | 22 (43%) |
| No preference | 17 (33%) | 17 (33%) |
| Different technique | 3 (6%) | 12 (24%)* |

Based on the actual amount of i.v. drug used, the cost of induction of anaesthesia with propofol was £3.23 (0.60). On the basis of one ampoule of propofol per patient, this cost increased to £3.88. The cost of induction with 8% sevoflurane was £1.95 (0.56), which was significantly cheaper compared with propofol.

The average time from the start of induction of anaesthesia to completion of surgery was 10.0 (3.9) min in the propofol group and 10.2 (3.2) min in the sevoflurane group. There were no significant differences between groups in terms of the highest or lowest anaesthetic concentrations required during maintenance or in the delivered anaesthetic concentration at the end of anaesthesia (2.3 (0.9) % and 2.3 (0.8) % in the propofol and sevoflurane groups, respectively). Emergence times in the sevoflurane induction group (5.2 (2.2) min) were significantly faster compared with the propofol group (7.0 (3.2) min). There were no differences in subsequent recovery events between the two groups. Postoperative nausea (two) and vomiting (two) occurred in four patients in the sevoflurane group compared with none in the propofol group. This difference was not statistically significant.

## Discussion

This is the first double-blind comparison of induction of anaesthesia with sevoflurane and an i.v. agent. Our results suggest that sevoflurane is a practical induction agent for unpremedicated adult day-case patients. Although induction times with sevoflurane were slower compared with propofol, this difference was not of great clinical significance and was not obvious to the observer. Furthermore, the higher incidence of apnoea with propofol resulted in the end-point of anaesthesia accompanied by regular spontaneous ventilation being achieved significantly earlier with sevoflurane. Although this difference was also of limited clinical significance, the transition from induction to maintenance with sevoflurane was significantly smoother compared with propofol, with fewer patients coughing after induction. This difference is probably explained by the fact that when anaesthesia has been induced by inhalation, the inspired and alveolar anaesthetic concentrations are almost equilibrated, so that subsequent small changes in the depth of anaesthesia are readily achieved. In contrast, after induction of anaesthesia with an i.v. agent, the drug rapidly redistributes leading to a decrease in the depth of anaesthesia. During this period, it is necessary to introduce the maintenance agent rapidly in order to re-establish an adequate depth of anaesthesia. At the same time, stimulating events such as patient positioning, skin cleaning and surgical incision may be occurring, requiring a relatively greater depth of anaesthesia. The fact that our patients predominantly exhibited coughing during this period suggests that anaesthesia was sufficient to prevent purposeful movements, but inadequate to suppress reflex stimulation resulting from the presence of an oral airway or manipulation of the anatomical airway. It is possible that the transition from induction to maintenance would have been smoother had a concentration of sevoflurane greater than 2% been introduced in patients receiving propofol. However, the results of a pilot study suggested that this concentration was the best compromise to use in both groups of patients without unblinding the investigation.

Induction of anaesthesia with sevoflurane was associated with several other advantages. MAP was better maintained with sevoflurane compared with propofol and while the difference may be of limited significance for healthy patients, the relative hypotension associated with propofol may be disadvantageous in the elderly and coronary artery disease. Emergence from sevoflurane anaesthesia also occurred significantly faster when sevoflurane was used for induction compared with propofol. This difference was presumably because of the residual sedative effect of propofol and would probably not have been detectable after longer operations. However, this difference of only 2 min is probably of little, if any, clinical significance. Induction of anaesthesia with 8% sevoflurane was also significantly cheaper compared with propofol. In practice, the cost of i.v. induction depends on how much induction agent is actually drawn up and whether the remainder of the ampoule is discarded or used for the next patient. Although the manufacturers of propofol state that their ampoules are for single patient use, ampoule sharing occurs commonly. We therefore calculated the cost of propofol induction using the two extremes, that is on the basis of the exact amount of propofol required and on the basis of one ampoule per patient. Sevoflurane induction was substantially cheaper by both methods of comparison. Our calculation did not include the cost of the plastic syringe or of lignocaine required to reduce pain on injection of propofol. Sevoflurane costs did not include the (small) cost of nitrous oxide or the cost of obtaining and servicing the sevoflurane vaporizer. Costs common to both techniques (e.g. face mask and breathing system) were also not included.

Despite these advantages of sevoflurane over propofol, inhalation induction of anaesthesia was not as popular with our patients as the use of an i.v. induction agent. Although the majority of patients either had no preference or would choose the same anaesthetic again, a significant minority were unwilling to undergo further inhalation induction and several patients described this technique as "unpleasant". The most likely explanation for this finding was the odour reported by most patients receiving sevoflurane, and which 29% of these patients described as "unpleasant". In contrast, previous open (non-blinded) evaluations of sevoflurane have reported its odour to be pleasant[9 10] and have found inhalation induction popular with almost all patients.[5 9–12] Our patient population was chosen because cystoscopy is a short procedure without significant postoperative pain. It was therefore considered that these patients would have optimum postoperative recall of the induction period. More prolonged anaesthesia may have modified patients' recall of the induction process in these previous investigations. Although this comparison was double-blind, the possibility of patient bias cannot be excluded. This is suggested by the fact that more than 60% of patients receiving propofol also reported a smell during induction and patients were more inclined to guess that they had received an inhalation induction irrespective of the technique used. Patients undergoing cystoscopy have usually received multiple previous anaesthetics, often with the same anaesthetist, and are accustomed to a particular routine. Furthermore, these relatively elderly patients often have had personal experience of inhalation induction with older, less satisfactory anaesthetic agents. As a result, these patients are suspicious of any changes in anaesthetic practice, as indicated by a relatively high rate of refusal to consent to participate in this clinical study compared with our previous experience with other studies. Patients receiving propofol for induction of anaesthesia may have detected a residual smell from previous use of the anaesthetic system. In an attempt to reduce this possibility, the breathing system was flushed with oxygen between patients until the investigator could no longer smell sevoflurane.

Previous investigations have also used lower concentrations of sevoflurane for induction of anaesthesia. A tidal breathing technique in which 5% sevoflurane was inspired from the outset induced anaesthesia in 109–153 s and was tolerated well by adult patients pretreated with fentanyl.[4 5] Stepwise induction with 0.5% sevoflurane increased to a maximum of 4.5% also induced anaesthesia in a similar time, but was associated with excitatory activity in more than 30% of patients.[9] This level of excitement does not appear to be observed with more rapid induction of anaesthesia.[9] The use of 8% sevoflurane in a tidal breathing technique allowed more rapid induction of anaesthesia than reported in previous investigations with 5% sevoflurane and was also not associated with significant excitatory activity. The previous highest concentration of sevoflurane used for induction was 7.5%.[10] These authors reported coughing in 25% of patients receiving a tidal breathing induction technique with 7.5% sevoflurane, although coughing was reduced to 5% by a vital capacity breathing technique.[10] Interestingly, we observed coughing during induction in only one patient (2%) during tidal breathing with 8% sevoflurane. In the former study, the anaesthetic system was primed with 7.5% sevoflurane (in nitrous oxide) before being applied to the patients, whereas our patients initially breathed oxygen from a system to which sevoflurane and nitrous oxide were subsequently added. Because of mixing with oxygen within the breathing system, the concentration of sevoflurane at the mask would have reached a maximum more slowly and this may have minimized coughing. Nevertheless, the relatively high number of patients who described the smell of sevoflurane as unpleasant may have been as a consequence of using 8% sevoflurane rather than the lower doses used previously. Further work is needed to determine the optimum sevoflurane concentration and administration technique for induction of anaesthesia.

Four patients experienced postoperative nausea and vomiting (PONV) when anaesthesia was induced and maintained with sevoflurane compared with none when propofol was the induction agent. Our study was not designed with sufficient power to detect such a small difference in PONV as statistically significant. Nevertheless, propofol is known to have antiemetic effects which may persist into the postoperative period even when it is used solely as an induction agent.[13 14] It is possible therefore that this small difference in PONV is genuine, although with the small numbers involved it is unlikely to be of great clinical importance.

In summary, 8% sevoflurane was a practical induction agent for use in unpremedicated adult patients undergoing day-case cystoscopy. A slightly slower induction time with sevoflurane was offset by a reduced incidence of apnoea, earlier establishment of regular spontaneous ventilation, smoother transition to the maintenance phase, minimal depression of MAP during induction of anaesthesia, earlier emergence from anaesthesia and reduced induction costs. Although induction of anaesthesia with sevoflurane was acceptable to the majority of patients, a significant minority found it to be unpleasant and would prefer a different technique in the future. While it is possible that this finding was unique to the particular patient population chosen, inhalation induction may not prove as universally popular as i.v. induction. However, the technique may be particularly beneficial to patients with needle phobias or difficult venous access.

## Appendix

### CALCULATION OF INDUCTION COSTS

*Propofol*

Cost (£)=(List price of ampoule / 20)×induction dose (ml)

*Sevoflurane*

Cost (£)=Induction time (min)×fresh gas flow (ml)×set %× price of bottle / (100-set %)×bottle size (ml)×ml vapour per ml liquid anaesthetic (182.7)

*List prices used for this study*

| | |
|---|---|
| Propofol | £3.88 for a 20-ml ampoule |
| Sevoflurane | £49 00 for a 100-ml bottle. |

# Rapid inhalation induction in children: 8% sevoflurane compared with 5% halothane

P. E. SIGSTON, A. M. C. JENKINS, E. A. JACKSON, M. R. J. SURY, A. M. MACKERSIE AND D. J. HATCH

## Summary

Sevoflurane has a lower blood-gas solubility and a less pungent odour than halothane; this may allow more rapid induction of anaesthesia. In a randomized, blinded study, we compared the induction characteristics of maximum initial inspired concentration of 8% sevoflurane and 5% halothane using conventional vaporizers in children aged 3 months to 3 years. There was no statistically significant difference in induction times between the two groups: mean times to loss of consciousness were 1 min 12 s (SD 18 s, range 40 s–1 min 44 s) for sevoflurane and 1 min 16 s (SD 17 s, range 50 s–1 min 52 s) for halothane, although these times were shorter than in previous studies using a gradual increase in vapour concentration. A small number of complications were noted in both groups, although none interfered with induction of anaesthesia. Struggling scores were lower in the sevoflurane group than in the halothane group (chi-square for trends=6.34, $P<0.02$). A significant number (11 of 15) of parents of children in the sevoflurane group who had previous experience of halothane induction preferred sevoflurane (chi-square for trends=4.03, $P<0.05$). We conclude that with this technique,induction was rapid with both sevoflurane and halothane. Our assessment of patient struggling and parents' perceptions suggests that induction with sevoflurane was more pleasant than with halothane. (*Br. J. Anaesth.* 1997; **78**: 362–365).

**Key words**

Sevoflurane is relatively non-irritant, and because of its low blood-gas solubility, it may have a rapid effect. It has recently been licensed for use in many countries around the world, and could therefore become the preferred inhalation induction agent for children.

Previous studies comparing the induction characteristics of sevoflurane and halothane in children used a technique in which the inspired concentrations were increased gradually, and only two of four showed that sevoflurane induced anaesthesia more rapidly than halothane.[1–4] It is possible however that a technique using high initial inspired concentrations of sevoflurane may be very rapid and we have therefore compared sevoflurane with halothane using maximum initial inspired concentrations delivered by conventional vaporizers in a randomized, blinded study.

## Patients and methods

We studied 52 patients, aged 3 months to 3 years, ASA I–III, allocated randomly to receive either sevoflurane or halothane for induction of anaesthesia. Patients were excluded if they had significant cardiac, respiratory, hepatic, renal, neurological or neuromuscular disease. There were two ASA III patients who had recurrent chest infections/ bronchiolitis from oesophageal stricture secondary to previous tracheo-oesophageal fistula and oesophageal reflux, respectively. The study was approved by the local Ethics Committee and parents gave informed written consent.

All patients received atropine 20 μg kg$^{-1}$ orally, 1 h before anaesthesia. No other premedication was prescribed and a parent was present at induction. Anaesthesia was induced by one of five anaesthetists using a standard technique. The anaesthetic was delivered by the use of a Mapleson F breathing system, with the anaesthetist holding the angle piece (without a mask) as close to the child's face as could be tolerated. The selected inhalation agent was administered with 66% nitrous oxide in oxygen at a vaporizer setting of either 5% for halothane or 8% for sevoflurane. The times taken to loss of consciousness (loss of eyelash reflex), acceptance of face mask and end of induction (small pupils, no gross bodily movements and regular respirations) were recorded for all patients by a trained observer. The

vaporizers were concealed by a screen and adjusted by an anaesthetic assistant, with both the anaesthetist and the observer blinded to the selection of the anaesthetic vapour. During induction, the vaporizer setting could be reduced by stepwise reductions at the request of the anaesthetist if clinically indicated. When induction was complete, anaesthesia was continued with 2% halothane.

As soon as possible during induction of anaesthesia, which took place either on the parent's lap or on a trolley, pulse oximeter saturations (Ohmeda Biox 3740), heart rate (Simonsen & Weel Diascope DS 521) and non-invasive arterial pressure measurements (Dinamap 1640) were recorded at 1-min intervals. In some children it was possible to apply the pulse oximeter probe before induction, and in the remainder it was applied immediately after loss of consciousness. The first arterial pressure recording was obtained 1 min after loss of consciousness in the majority of cases. Any untoward events (cough, laryngospasm, secretions, breath-holding, vomiting, bronchospasm and excitement) were noted and scored (1 mild, 2=moderate, 3=severe). Movements before loss of consciousness were classified as struggling and those afterwards as excitement. A struggling score of 1 was given for head movement only, 2 for mild struggling with head and limb movements and 3 for more severe struggling. All observations and measurements were made and recorded by the same trained observer throughout the study. At the end of induction the anaesthetist was asked to give an opinion on which agent had been used.

Parents were interviewed the following day, either on the ward or by telephone if the child had already been discharged. They were asked specific questions where appropriate about how this induction compared with previous experience of inhalation induction of anaesthesia with halothane (How did this anaesthetic induction compare with previously? Better, identical or worse?).

Randomization was performed with random number tables. The Student's unpaired $t$ test was used for comparisons of induction times and lowest oxygen saturations. The chi-square test for trends was used to compare struggling scores and parental comparison with previous halothane anaesthesia. A test of the difference in proportions was used to compare the incidence of excitement with the two agents. Statistical significance was accepted when $P<0.05$.

## Results

Of the 52 patients studied, 27 received halothane and 25 received sevoflurane. One patient in the halothane group did not lose consciousness within 5 min, raising suspicion of equipment malfunction. The vaporizers were uncovered and the sevoflurane vaporizer was removed from the back bar. Induction then continued successfully with halothane. This patient was removed from the study, leaving complete data on 26 patients in the halothane group and 25 in the sevoflurane group. The distribution of age, weight and ASA grading was similar between the two groups (table 1). There were more boys because of inclusion of urological patients in the study.

*Table 1* Distributions of age, body weight, sex and ASA status in children anaesthetized with either sevoflurane or halothane (mean (SD or range) or number)

| | Halothane | Sevoflurane |
|---|---|---|
| *n* | 26 | 25 |
| Age (months) | 17.7 (3.1–30.4) | 16.0 (4.5–29.1) |
| Weight (kg) | 10.8 (3.1) | 10.6 (2.2) |
| Sex, (M/F) | 21/5 | 14/11 |
| ASA I/II/III | 16/9/1 | 12/12/1 |

Mean time to achieve loss of consciousness (loss of eyelash reflex) was shorter with sevoflurane (1 min 12 s; SD 18 s; range 40 s–1 min 44 s) than with halothane (1 min 16 s; 17 s; 50 s–1 min 52 s) but this small difference was not statistically significant ($P$=0.43) (fig. 1). Similarly, mean time to acceptance of the face mask (fig. 2) and mean time taken to complete induction (fig. 3) were slightly shorter in the sevoflurane group but the differences were not statistically significant between the two groups ($P$=0.47 and $P$=0.25, respectively). Loss of consciousness was achieved in less than 1 min in six patients in the sevoflurane group and in eight patients in the halothane group. In one patient in the

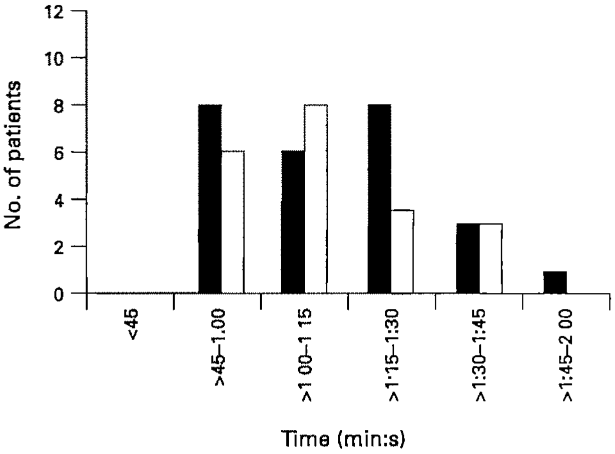

*Figure 1* Distribution of the time taken to loss of eyelash reflex in children who received induction of anaesthesia with either sevoflurane (☐) or halothane (■).

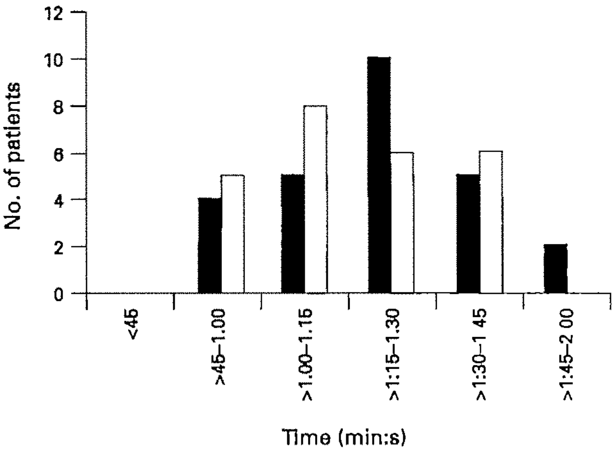

*Figure 2* Distribution of the time taken to acceptance of a face mask in children who received induction of anaesthesia with either sevoflurane (☐) or halothane (■).

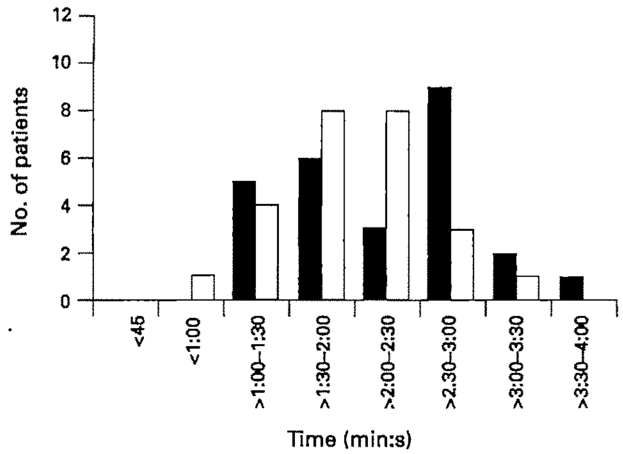

*Figure 3* Distribution of the time taken to complete induction of anaesthesia in children who received either sevoflurane (☐) or halothane (■).

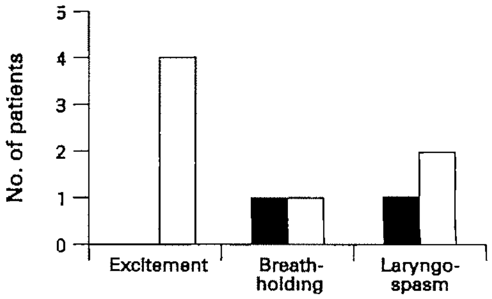

*Figure 5* Number of children who became excited, held their breath or had laryngospasm during induction of anaesthesia with either sevoflurane (☐) or halothane (■).

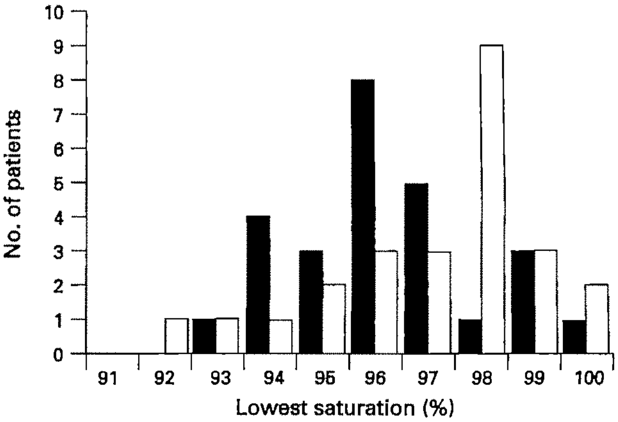

*Figure 6* Lowest pulse oximetry readings in children anaesthetized with either sevoflurane (☐) or halothane (■).

sevoflurane group, induction was completed within 1 min.

Seventeen children who received halothane were classified as having severe struggling compared with 10 in the sevoflurane group (fig. 4). Struggling scores were significantly lower in the sevoflurane group than in the halothane group (chi-square for trends=6.34, $P<0.02$).

Complications are summarized in figure 5; all were short lived and did not interfere with induction of anaesthesia. Excitement, defined as movements occurring after loss of consciousness, occurred in four patients in the sevoflurane group, two episodes of which were classified as severe. One patient who received sevoflurane demonstrated mild excitement, breath-holding and laryngospasm. The difference in the incidence of excitement was not statistically significant ($P=0.11$). No child vomited, had excess secretions, bronchospasm or coughed. Lowest and highest heart rates and arterial pressures were similar in both groups. Three patients had oxygen saturation values less than 94%, two in the sevoflurane group and one in the halothane group (fig. 6), but no patient had saturations less than 92%. Comparison of the lowest oxygen saturations showed no statistically significant differences between the two groups ($P=0.12$). There were no clinically significant episodes of desaturation in any patient. During induction of five patients, after loss of consciousness, the anaesthetist requested a reduction in the inspired vapour concentration to 50% of the initial setting. In one case this reduction was because of bradycardia (heart rate decreased from 162 to 71 beat $\text{min}^{-1}$) while receiving halothane and in the other cases (two in each group), this reduction was in response to clinically assessed hypoventilation.

Twenty-nine patients had undergone previous gaseous induction with halothane (15 in the sevoflurane group). The parents of 11 sevoflurane patients and three halothane patients preferred the study induction to previous experience (fig. 7). This difference was statistically significant (chi-square for trends=4.03, $P<0.05$).

The anaesthetists' opinions of which agent had been used were correct in 23 of 25 patients in the sevoflurane group, but in only 17 of 27 patients in the halothane group.

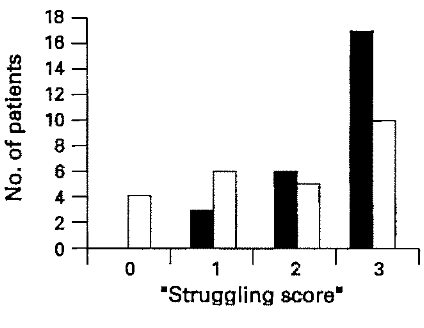

*Figure 4* Assessment of struggling of children who received induction of anaesthesia with either sevoflurane (☐) or halothane (■). 0=None, 1=head movement only, 2=head and limb movement, 3=severe struggling.

## Discussion

Inhalation induction remains a widely used technique in paediatric anaesthesia, particularly for small children in whom i.v. cannulation may be difficult. Because of its lack of airway irritation and smooth, relatively rapid induction qualities, halothane has remained the preferred agent for inhalation induction in children, despite its unpleasant odour, potential for hepatic damage[5] and increased incidence of arrhythmias. Sevoflurane has a lower blood-gas solubility and a less pungent odour, suggesting that induction may be more rapid than with halothane with a low incidence of complications during induction.

Our study demonstrated no significant difference between induction times for the two agents at maximum initial inspired concentrations. The sample size of 52 patients gave 80% power at the 5% level of detecting a difference in induction times of 14 s. However, the use of maximum inspired concentrations allowed us to achieve shorter induction times: 1 min 12 s and 1 min 16 s with sevoflurane and halothane, respectively, compared with 1 min 41 s and 2 min 17 s in a previous study undertaken at this institution using a gradual increase in vapour concentration.[1] These short induction times are in keeping with previous studies examining the use of high initial inspired concentrations of sevoflurane.[6 7]

The more rapid induction seen with sevoflurane compared with halothane in previous studies may reflect the fact that equivalent minimum alveolar concentrations were not used. We chose to compare inspired concentrations of 8% sevoflurane and 5% halothane, as these were the maximum concentrations that could be delivered by the vaporizers available to us. Based on published data, Lerman regards an inspired concentration of 7% sevoflurane as equivalent to 4.5% halothane, a similar ratio to that used in this study.[8] He does not believe that induction with sevoflurane should be faster than with halothane when over-pressure techniques are used, and the results of this study appear to support this view. To confirm this point, however, the anaesthetic would need to be delivered via a mask that was applied firmly to the face from the beginning of induction. This would probably be unacceptable in children when over-pressure is used, at least for induction with halothane.

Sevoflurane was not associated with any major airway complications, with a few episodes of mild breath-holding and laryngospasm. Although the use of atropine is not universal in this age group, unpublished data from our own laboratory suggest that the incidence of airway complications is higher in infants when it is not used. It is possible that the use of atropine as a premedicant in this study was a factor in minimizing the incidence of airway problems during induction. Excitement, a term used to describe involuntary movements occurring after loss of consciousness, occurred exclusively in the sevoflurane group, but did not interfere with the course of induction. This excitement occurred with a lower frequency than documented in previous studies[1 2] using a technique involving a gradual increase in sevoflurane concentration.

It is difficult to determine preference for any particular induction agent in patients of this age group, although adult volunteers have found the smell of sevoflurane more acceptable than halothane.[6] We have attempted to assess this factor, by assessing the degree of patient struggling during induction, and questioning the parents on the following day. Our results demonstrated that struggling was more severe in the halothane group. The majority of parents whose children received sevoflurane felt that the present anaesthetic was preferable to their previous halothane anaesthetic. We believe that these two results suggest a more pleasant induction for children with sevoflurane.

We did not detect any significant difference in the time taken to induce anaesthesia with sevoflurane compared with halothane when used with high initial inspired concentrations. Although the trained observer was at a sufficient distance from the patient so as not to be able to detect the odour, we suspected that blinding of the anaesthetists would be confounded by their ability to detect which agent was being administered. This was found not to be the case. Despite Lerman's prediction that induction times for the two agents would be similar when over-pressure was used, the speed of induction with halothane surprised us, and previously held assumptions may explain why the anaesthetists erroneously thought that 10 patients in the halothane group had been given sevoflurane.

The significant difference in struggling scores and in parental preference suggest that in children aged 3 months to 3 years, sevoflurane provided more pleasant induction.

# Halothane–propofol anaesthesia for tracheal intubation in young children

D. HANSEN, W. SCHAFFARTZIK, D. DOPJANS, E. HEITZ AND H. W. STRIEBEL

## Summary

In this double-blind, randomized study, we have investigated 100 healthy children, aged 3–6 yr. We compared intubating conditions and cardiovascular changes during light halothane anaesthesia and propofol 3 mg $kg^{-1}$ with those during deep halothane anaesthesia. Light halothane anaesthesia was defined as an end-tidal concentration of 1%, deep halothane anaesthesia as 2%. Intubating conditions were graded according to ease of laryngoscopy, vocal cord position and coughing. There were no statistically significant differences in the assessment of intubating conditions between the two groups; 94% of the children in the 1% halothane–propofol group and 100% of the children in the 2% halothane group had acceptable intubating conditions. Systolic arterial pressure decreased by 13% in the 1% halothane–propofol group compared with 20% in the 2% halothane group ($P<0.01$). (*Br. J. Anaesth.* 1997; **78**: 366–369).

**Key words**
Anaesthesia, paediatric. Anaesthetics i.v., propofol. Anaesthetics volatile, halothane. Intubation tracheal. Children.

The routine use of suxamethonium to facilitate tracheal intubation in children is controversial.[1] Severe side effects such as cardiac arrest and death have been reported in young children.[2] Even the use of non-depolarizing neuromuscular blocking agents may be associated with undesirable effects, such as prolonged neuromuscular block or the need to antagonize paralysis.[3] Therefore, tracheal intubation without the use of neuromuscular blocking agents is an alternative, especially for short procedures in paediatric anaesthesia. Deep halothane anaesthesia is suitable for tracheal intubation in children, but this inhalation agent is associated with cardiovascular depression.[4] Propofol has been studied for tracheal intubation in adults and children.[5–9] Adjuvant agents such as alfentanil and lignocaine improve intubating conditions.[5 9 10] A common side effect of propofol administration is pain on injection which can cause problems, especially in paediatric anaesthesia.[11–16] This can be avoided if propofol is administered after inhalation induction of anaesthesia by halothane. However, to date, no study has been undertaken on the intubating conditions and cardiovascular effects of propofol during halothane anaesthesia.

The aim of this study was to compare in children intubating conditions and cardiovascular side effects of light halothane anaesthesia in combination with propofol administration with deep halothane anaesthesia. Because propofol has not yet been licensed for children aged less than 3 yr, we limited this study to children aged 3–6 yr.

## Patients and methods

The Ethics Committee of the Hospital approved the study and written informed consent was obtained from parents.

In a prospective, randomized, double-blind design, we studied healthy children, aged 3–6 yr, ASA I or II. Children with a history of difficulties in tracheal intubation were excluded. All children were premedicated with midazolam 0.5 mg $kg^{-1}$ rectally, 30 min before induction of anaesthesia.

Fifty children being recruited into one of two groups: 2% halothane group=deep halothane anaesthesia, defined as an end-tidal halothane concentration of 2%; halothane–propofol group=light halothane anaesthesia, defined as an end-tidal halothane concentration of 1% combined with propofol 3 mg $kg^{-1}$. An independent nurse anaesthetist prepared syringes with propofol and placebo. Propofol was used as a 1% solution; 10% lipid emulsion was used as placebo.

On arrival in the anaesthetic room an electrocardiogram, pulse oximeter and non-invasive arterial pressure monitor (CMS-monitor, Hewlett-Packard) were attached. A side-stream connector for measurement of end-tidal halothane concentration and carbon dioxide was introduced between the face mask and anaesthetic tubing (side-stream gas analyser, Hewlett-Packard, M1025A).

Anaesthesia was induced with increasing concentrations of halothane and 67% nitrous oxide in oxygen, with a fresh gas flow of 6 litre $min^{-1}$, using a

D. HANSEN, MD, W. SCHAFFARTZIK, MD, D. DOPJANS, MD, E. HEITZ, H. W. STRIEBEL, MD, Department of Anaesthesiology and Intensive Care Medicine, Benjamin Franklin Medical Centre, Free University of Berlin, Hindenburgdamm 30, 12200 Berlin, Germany. Accepted for publication: December 16, 1996.

Correspondence to D. H.

semi-closed circle system. When the child was asleep, an i.v. cannula was sited and the vaporizer was set to 3% in the 2% halothane group and to 1–1.5% in the halothane–propofol group. End-tidal halothane concentrations of 2% and 1%, respectively, were reached within 3–5 min. Spontaneous breathing was assisted and mild hyperventilation to an end-tidal carbon dioxide partial pressure ($P\text{E}'_{\text{CO}_2}$) of 4.2–4.4 kPa was established. Two anaesthetists were involved. Anaesthetist I performed the anaesthesia and anaesthetist II was in charge of the vaporizer and gas analyser. The vaporizer and gas analyser were not visible to anaesthetist I. Anaesthetist II gave commands to maintain a $P\text{E}'_{\text{CO}_2}$ of 4.2–4.4.kPa. He also set the vaporizer to maintain an end-tidal halothane concentration of 2% in the 2% halothane group and 1% in the halothane–propofol group. When the desired end-tidal halothane concentration was reached, 0.3 ml $\text{kg}^{-1}$ of the placebo (2% halothane group) or the propofol solution (halothane–propofol group) were administered over 15 s. Ninety seconds later tracheal intubation was performed. If tracheal intubation was not possible, suxamethonium 1.5 mg $\text{kg}^{-1}$ was given to facilitate intubation. After intubation, the lungs of all patients were ventilated with 1% halothane and 67% nitrous oxide in oxygen.

Heart rate (HR), arterial haemoglobin oxygen saturation ($Sp_{\text{O}_2}$) and arterial pressure (SAP) were noted before induction, after induction when end-tidal halothane concentration had reached 2% and 1%, respectively, 90 s after propofol or placebo administration, immediately after intubation, and 1 and 3 min after intubation. If HR was less than 80 beat $\text{min}^{-1}$, atropine 0.01 mg $\text{kg}^{-1}$ was given.

Intubating conditions were assessed by anaesthetist I on the basis of the scoring system devised by Helbo-Hansen, Ravlo and Trap-Andersen.[17] Ease of laryngoscopy, vocal cord position and coughing were estimated on four-point scales. Intubating conditions were judged acceptable when each individual category score was 2 or less.

The chi-square test was used for non-parametric data. Student's *t* test with Bonferrroni correction was used for parametric data. $P<0.05$ were regarded as statistically significant.

## Results

We studied 100 children, aged 3–6 yr. The two groups were comparable in age, weight and sex (table 1). Baseline values of SAP and HR did not differ significantly. All children in the 2% halothane group showed acceptable intubating conditions compared with 94% in the halothane–propofol group (table 2) (ns). For three children in the halothane–propofol group, coughing was judged to be moderate; in one of these children closing of the vocal cords was assessed and in another child the vocal cords were closed. In this child suxamethonium was given to facilitate tracheal intubation.

In both groups HR decreased significantly after induction of anaesthesia (fig. 1). Three children in the 2% halothane group and two children in the halothane–propofol group received atropine after induction because HR was less than 80 beat $\text{min}^{-1}$. After administration of atropine HR and SAP increased in these children. For this reason HR and SAP values of these five children are not given in figure 1 and table 3. After administration of propofol

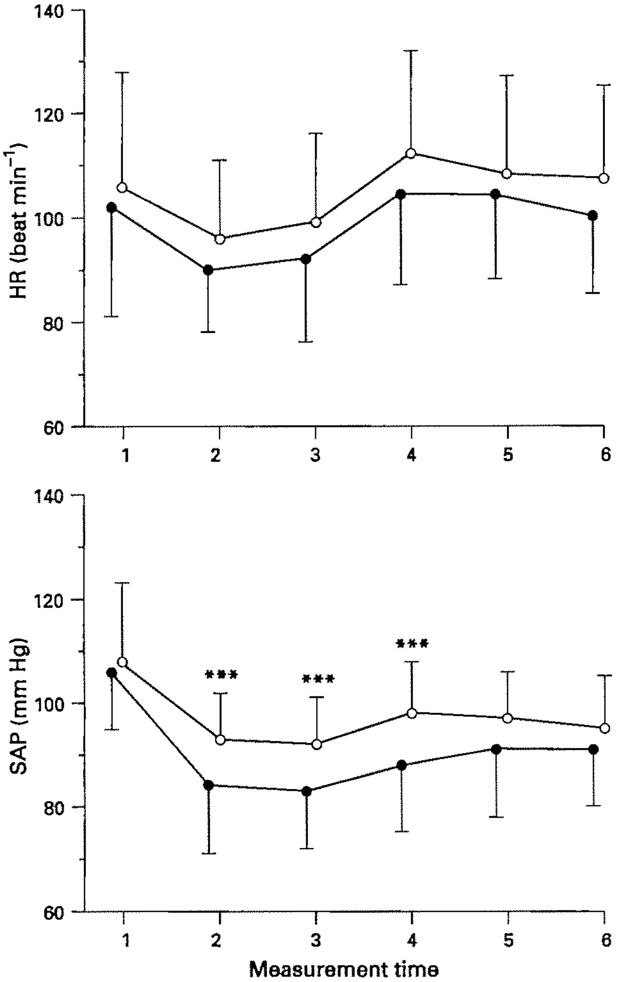

*Figure 1* Heart rate (HR) and systolic arterial pressure (SAP) responses in the 2% halothane (●) ($n$=47) and 1% halothane–propofol (○) ($n$=48) groups (mean (SD)). Measurement times: 1=before induction of anaesthesia; 2=after induction of anaesthesia; 3=after administration of propofol or placebo; 4=after tracheal intubation; 5=1 min after intubation; 6=3 min after intubation. ***$P$<0.001 between groups.

HR remained constant. After intubation HR increased in both groups. There were no significant differences in HR between the two groups. After induction of anaesthesia SAP decreased by 20% in the 2% halothane group compared with only 13% in the halothane–propofol group ($P$<0.01, table 3). After administration of propofol or placebo, SAP did not change significantly. After tracheal intubation SAP increased slightly, but SAP was still significant lower in the 2% halothane group.

## Discussion

Although suxamethonium produces good intubating conditions and has been used widely during the past 40 yr in paediatric anaesthesia, routine use in children is controversial because of its potential to induce masseter muscle spasm, malignant hyperthermia, hyperkalaemia and cardiac arrest.[1,2,18] Nondepolarizing neuromuscular blocking agents such as vecuronium or atracurium are poor alternatives because anaesthetic recovery may be delayed and neuromuscular block may be prolonged.[3]

Tracheal intubation without the use of neuromuscular blocking agents is an alternative. Deep halothane anaesthesia for tracheal intubation has been studied widely in children.[4,19,20] End-tidal halothane concentrations of 1.85% result in good intubating conditions in 95% of children aged 2–6 yr.[19] In a previous study, we assessed acceptable intubating conditions in 96% of children aged 1–5 yr at an end-tidal halothane concentration of 2%.[4] These findings were confirmed in the present study. Intubating conditions were evaluated as acceptable in all children in the 2% halothane group.

The most common side effect of deep halothane anaesthesia is cardiovascular depression. A decrease in arterial pressure of 18% has been reported by several authors[4,21,22] and this is similar to the changes observed in this study. The reduction in SAP during halothane anaesthesia is caused by a decrease in stroke volume and cardiac index.[21]

It is also possible to perform tracheal intubation without neuromuscular block by administration of propofol. McKeating, Bali and Dundee showed that conditions for laryngoscopy after propofol were superior to induction of anaesthesia with thiopentone in adults.[23] Addition of the short-acting opioid alfentanil further improved intubating conditions in adults[5–7] and children.[8,9] Intubating conditions were assessed as acceptable in 80% of children after alfentanil 15 μg kg$^{-1}$ and propofol 2.8–3.4 mg kg$^{-1}$.[9] The same incidence (80%) of acceptable intubating conditions was found by Steyn and co-workers in children aged 2–14 yr after alfentanil 15 μg kg$^{-1}$ and propofol 3–4 mg kg$^{-1}$ using the same intubating condition score as in this study.[8] We found a higher incidence (94%) of acceptable intubating conditions in children after administration of propofol 3 mg kg$^{-1}$ during 1% halothane anaesthesia. The combination of propofol and halothane seemed to decrease pharyngeal reflexes more reliably than propofol–opioid anaesthesia.

Induction of anaesthesia by inhalation of halothane avoids the problems of inserting a cannula into a vein in awake children and pain on injection of propofol, which is common, especially in children. The incidence has been reported as 6.6–50%.[12–16,24] Pretreatment with alfentanil or lignocaine reduces the incidence of pain only to 4–40%.[11]

The cardiovascular changes which were observed in the 1% halothane–propofol group were surprising. During 1% halothane anaesthesia SAP decreased by 13%. Administration of propofol 3 mg kg$^{-1}$ did not lead to a further decrease in arterial pressure. This is in contrast with other studies. Most authors reported a decrease in SAP by 15–28 % after propofol administration[12,14,16,25] caused by a decrease in stroke volume, cardiac index and systemic vascular resistance.[25] In all of these studies, anaesthesia was induced with propofol and maintained with halothane and nitrous oxide. The haemodynamic measurements were assessed when halothane had already been added to propofol. Therefore, these studies do not describe the haemodynamic changes of a single dose of propofol 2–3 mg kg$^{-1}$ in children. Murray and colleagues reported the haemodynamic effects caused by continuous infusion of propofol 0.4 mg kg$^{-1}$ min$^{-1}$ (with nitrous oxide) in children with a mean age of 4.8 yr. MAP decreased by 24% and stroke volume decreased by 22%.[26] As the dose of 0.4 mg $kg^{-1}$ $min^{-1}$ is very high, it is questionable if these results reflect the haemodynamic effects of a single dose of propofol. Further investigations are necessary to describe the cardiovascular effects of propofol used as a single dose or in combination with other anaesthetic agents in children.

We conclude that propofol administration during 1% halothane anaesthesia was a reliable method for tracheal intubation in children aged 3–6 yr. The incidence of acceptable intubating conditions was comparable with that during deep halothane anaesthesia, defined as an end-tidal halothane concentration of 2%, but cardiovascular depression was less during 1% halothane–propofol anaesthesia.

# Minimum alveolar concentration of desflurane for tracheal extubation in deeply anaesthetized, unpremedicated children

K. A. W. CRANFIELD AND L. M. BROMLEY

## Summary

We have studied 25 children, aged 4–9 yr, to determine the minimum alveolar concentration (MAC) of desflurane at which safe tracheal extubation can be performed in deeply anaesthetized children. The end-tidal concentration of desflurane was noted at tracheal extubation. Successful extubation was defined as one in which there was no coughing or bucking on the tracheal tube during suctioning of the pharynx, no movement or coughing within 1 min of tracheal extubation and no breath-holding or laryngospasm after extubation. Successful extubation was followed by extubation at a concentration of 0.5% less, and so on in subsequent subjects, until unsuccessful extubation occurred. After a reaction, the percentage was increased in the next patient, continuing up and down in pairs, until the required number of subjects was achieved. In 50% of children aged 4–9 yr, tracheal extubation may be accomplished without coughing or moving at an end-tidal concentration of 7.7%. The end-tidal concentration of desflurane to achieve satisfactory extubation in 95% of children was 8.5%. (*Br. J. Anaesth.* 1997; **78**: 370–371).

**Key words**
Anaesthetics volatile, desflurane. Intubation tracheal. Potency, anaesthetic, MAC. Anaesthesia, paediatric. Children.

Extubation of the trachea can be performed while the patient is deeply anaesthetized, or awake in a patient who has intact airway reflexes. The advantages of so called "deep extubation" are a reduction in coughing and other airway complications in situations where this is undesirable, for example during neurosurgery. Extubation during deep anaesthesia may also result in improved haemoglobin oxygen saturation compared with "awake extubation".[1]

The disadvantages of "deep extubation" are continuation of suppression of the laryngeal reflexes induced by general anaesthesia. This prevents coughing and may result in contamination of the airway. Partial or total airway obstruction may not be recognized.

These disadvantages should become less significant with an agent such as desflurane. Its low blood-gas solubility coefficient results in extremely rapid emergence and it would therefore be an ideal agent for "deep extubation".[2]

## Patients and methods

After obtaining Ethics Committee approval and informed consent from the parents or guardians, we studied 25 children, aged 4–9 yr (mean 6.0 yr). The children were ASA I or II, undergoing ear, nose and throat surgery: 10 patients were undergoing adenotonsillectomy, eight tonsillectomy and seven adenoidectomy with insertion of grommets.

The children were unpremedicated. Anaesthesia was induced using an inhalation technique with halothane and nitrous oxide in oxygen. An Ayre's T piece was used at fresh gas flows of 2.5 times the patient's minute volume. The trachea was intubated during deep halothane anaesthesia. When the airway was secure, halothane and nitrous oxide were discontinued and anaesthesia was maintained with desflurane in oxygen. The children were allowed to breathe spontaneously. Ventilation was assisted where necessary to maintain normocapnia.

End-tidal desflurane and carbon dioxide concentrations were measured using the Datex Capnomac Ultima monitor, sampling from the tracheal tube connector. The pharynx was suctioned before extubation and the patient's trachea extubated in the left lateral position while noting the end-tidal concentration of desflurane. There was no residual halothane or nitrous oxide at the time of extubation. A steady state concentration had been maintained for at least 10 min.

Unsatisfactory extubation was defined as one which resulted in coughing or bucking during suctioning of the pharynx, moving or coughing within 1 min of tracheal extubation, or produced laryngospasm or breath-holding. The investigator observing the response to extubation was independent from the anaesthetist responsible for controlling the end-tidal desflurane concentration. We chose a starting concentration of 12% because research on other volatile agents has shown that the optimal level for "deep extubation" is twice the MAC.[1]

*Present address: Department Of Anaesthetics, Northwick Park Hospital, Watford Road, Harrow, Middlesex HA1 3UJ.

After successful extubation, the trachea of the next patient was extubated at 0.5% less than the previous patient. This continued in a stepwise fashion until unsuccessful extubation. The following patient's trachea was extubated at 0.5% more than the reactor, continuing up and down in a stepwise manner until the required number of patients was achieved.

When tracheal extubation was achieved, the children were given i.v. analgesia.

The number of patients and the methodology were modelled on a previous similar study to establish the safe dose of isoflurane for "deep extubation".[3]

### STATISTICAL ANALYSIS

Probit analysis was used to estimate the end-tidal concentration of desflurane at which extubation was achieved satisfactorily in 50% ($\text{MAC}_{\text{EX50}}$) and 95% ($\text{MAC}_{\text{EX95}}$) of patients. These were 7.7% (95% confidence limits 6.77–8.22%) and 8.5% (8.03–14.5%), respectively.

## Results

Figure 1 shows the response of each individual to tracheal extubation at varying end-tidal concentrations of desflurane.

Using the Mann–Whitney *U* test and the Wilcoxon rank sum *W* test, the ages, weights and steady state times did not influence the outcome of extubation.

Two patients developed laryngospasm at tracheal extubation; in both the trachea was extubated at end-tidal concentrations of 7.0% desflurane. One patient had undergone adenotonsillectomy and the other tonsillectomy alone. Laryngospasm resolved with application of positive pressure until the spasm settled. Oxygen saturation of both patients remained greater than 94%.

## Discussion

The $\text{MAC}_{\text{EX50}}$ in a deeply anaesthetized patient was established for isoflurane by Neelakanta and Miller.[3] This was defined as the alveolar concentration of inhalation anaesthetic at which 50% of patients undergoing tracheal extubation cough or move within 1 min of extubation or develop breath-holding or laryngospasm immediately after tracheal extubation.

"Deep extubation" is a useful technique in circumstances where coughing on the tracheal tube is undesirable. It has been suggested that "deep extubation" reduces episodes of desaturation in the emergence phase of anaesthesia.[1,4] Opponents of "deep extubation" argue that while the reflexes in the airway are obtunded, aspiration of foreign material can occur. Patients are also at risk of partial or total airway obstruction. Recovery staff need to be adequately trained and understand the possible complications involved in caring for the deeply unconscious patient.

Previous data suggested that despite its irritant nature, there is no increased incidence of coughing or airway irritation during emergence from desflurane anaesthesia.[2] The low blood-gas solubility coefficient of desflurane (0.42) and its low tissue–blood partition coefficient allow a more rapid decrease in the rate of elimination ($F\text{A}/F\text{A}_0$) compared with isoflurane and halothane. This makes it an ideal agent for "deep extubation" as it is eliminated rapidly, allowing prompt return of upper airway reflexes. Several studies have shown its rapid recovery characteristics in children and adults.[5,6]

In conclusion, the safe MAC value of desflurane for successful deep extubation in 50% of anaesthetized school-aged children was 7.7%. This is approximately the same value quoted for the MAC of this agent in children of 5–12 yr (established as mean 7.98 (SD 0.43)%). We have demonstrated that the safe concentration in oxygen was approximately 8.5% and therefore we would expect that safe "deep extubation" should be possible at a concentration of at least 8.0% in the presence of nitrous oxide and analgesics.

# Increase in serum creatine phosphokinase concentrations after suxamethonium during sevoflurane or isoflurane anaesthesia in children

A. Kudoh, T. Sakai, H. Ishihara and A. Matsuki

## Summary

We have studied whether sevoflurane or isoflurane anaesthesia modulates the effect of suxamethonium on serum concentrations of enzyme markers of skeletal muscle function in paediatric patients. Eighty patients undergoing bilateral tonsillectomy, aged 5–12 yr, were allocated randomly to receive anaesthesia with either sevoflurane and nitrous oxide or isoflurane and nitrous oxide. Serum creatine phosphokinase (CK), aspartate aminotransferase (AST), alanine aminotransferase (ALT) and lactate dehydrogenase (LDH) concentrations were measured before, and at 30 min and 20 h after induction of anaesthesia. Mean CK concentrations increased from 97.0 (SD 17.3) to 478 (170) iu litre$^{-1}$ in the sevoflurane group and from 86.9 (22.4) to 628 (223) iu litre$^{-1}$ in the isoflurane group, 20 h after induction of anaesthesia. Mean peak serum CK concentration in the sevoflurane group (478 (170) iu litre$^{-1}$) was significantly less ($P<0.05$) than that in the isoflurane group (628 (223) iu litre$^{-1}$). Mean serum AST concentration increased from 17.5 (4.9) to 31.7 (3.5) iu litre$^{-1}$ in the sevoflurane group and from 17.3 (2.4) to 34.8 (5.7) iu litre$^{-1}$ in the isoflurane group, 20 h after induction of anaesthesia. Mean peak serum AST concentrations in the sevoflurane group were significantly lower ($P<0.05$) than those in the isoflurane group. There were no significant differences in serum ALT or LDH concentrations between the groups either before or after anaesthesia. We conclude that administration of suxamethonium during either sevoflurane or isoflurane anaesthesia caused a marked increase in serum CK concentrations in paediatric patients. The clinical significance of this finding is uncertain. (*Br. J. Anaesth.* 1997; **78**: 372–374).

**Key words**
Anaesthesia, paediatric. Anaesthetics volatile, sevoflurane. Anaesthetics volatile, isoflurane. Enzymes, creatine phosphokinase. Neuromuscular block, suxamethonium. Children.

Sevoflurane has a low blood-gas partition coefficient (0.63) and the lowest pungency[1–3] of commercially available inhalation anaesthetics. Thus a rapid increase in alveolar and tissue anaesthetic partial pressure is achieved easily during induction with sevoflurane, and in children its haemodynamic effects are less than that of halothane.[4] Because of these characteristics, this agent is the most frequently used for induction of anaesthesia in paediatric patients.

Serum creatine phosphokinase (CK) concentrations increase more in children than in adults after i.v. administration of suxamethonium during either halothane or enflurane anaesthesia.[5 6] Peak serum CK concentrations are reported to occur at 9–24 h after administration of suxamethonium. However, data on serum CK concentrations for this period during sevoflurane and isoflurane anaesthesia have not been reported. Thus this study was designed to determine serum concentrations of CK and other enzymes before and after suxamethonium during sevoflurane or isoflurane anaesthesia in paediatric patients.

## Patients and methods

The study was approved by the Institutional Ethics Committee and informed consent was obtained from a parent of each patient. We studied 80 ASA I paediatric patients, aged 5–12 yr, undergoing bilateral tonsillectomy.

Patients were allocated randomly to one of two groups to receive either sevoflurane or isoflurane. All patients were premedicated with oral diazepam 0.3 mg kg$^{-1}$, 60 min before induction of anaesthesia. Anaesthesia was induced in 40 patients with 5.0% sevoflurane in combination with nitrous oxide 2 litre min$^{-1}$ and oxygen 2 litre min$^{-1}$. Anaesthesia was maintained with 2.5% sevoflurane and 50% nitrous oxide in oxygen. The remaining 40 patients received 3.0% isoflurane and nitrous oxide 2 litre min$^{-1}$ and oxygen 2 litre min$^{-1}$ during induction. Anaesthesia was maintained with 1.5% isoflurane and 50% nitrous oxide in oxygen. I.v. suxamethonium 1 mg kg$^{-1}$ was given to facilitate tracheal intubation in

Accepted for publication: December 5, 1996.
*Address for correspondence: Department of Anesthesiology and Pain Management, Cook County Hospital, 637 S. Wood St, Room #427, Chicago, IL 60612, USA.

both groups. End- expiratory concentrations of oxygen, carbon dioxide and anaesthetics were monitored using a 5250 RGM analyser (Ohmeda, Madison, WI, USA). Lactated Ringer's solution was infused at a rate of 4 ml kg$^{-1}$ h$^{-1}$ to all patients. The lungs were ventilated mechanically to maintain $PE'_{CO_2}$ at 4.8–5.6 kPa. Rectal temperature was monitored continuously with an electric thermistor and maintained at 36.5–37.5 °C using a warming blanket. Postoperative pain relief was provided by rectal diclofenac sodium 12.5–25 mg every 6 h as needed.

Fasciculations after administration of suxamethonium and postoperative muscle pain the day after surgery were evaluated in all patients. Blood samples were obtained just before, and 30 min and 20 h after induction of anaesthesia. CK was measured using a modification of the Rosalki's method with a Paramax kit from Baxter (Deerfield, USA).[7] Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) concentrations were measured using a modification of the method of the Scandinavian Society of Clinical Chemistry with a Paramax kit from Baxter (Deerfield, USA).[8] Lactate dehydrogenase (LDH) concentration was measured according to a modification of the method of Gay and colleagues using a Paramax kit.[8] The CK method has a sensitivity of 0.091 mAd min$^{-1}$ iu$^{-1}$ litre$^{-1}$ and a coefficient of variation (cv) of less than 2%. The AST, ALT and LDH assays have a sensitivity of 0.182 mAd min$^{-1}$ iu$^{-1}$ litre$^{-1}$ and a cv of less than 7%. Normal ranges are 38–173 iu litre$^{-1}$ for CK, 12–45 iu litre$^{-1}$ for AST, 7–40 iu litre$^{-1}$ for ALT and 180–387 iu litre$^{-1}$ for LDH.

Data, expressed as mean (SD), were analysed using the Student's $t$ test for paired and unpaired samples. $P<0.05$ was considered statistically significant.

## Results

There were no significant differences between the two groups in age, weight, duration of surgery and anaesthesia, or rectal temperature (table 1). Laryngospasm, bronchospasm and masseter muscle spasm did not occur in any patient during induction of anaesthesia. Systolic and diastolic arterial pressures and heart rate during anaesthesia were similar in both groups.

Postoperative muscle pain was reported by 33% of patients in the sevoflurane group and by 43% in the isoflurane group. There were no significant differences in serum concentrations of CK or AST between patients with and without muscle pain. Fasciculations were observed in 18% of patients in the sevoflurane and in 15% of patients in the isoflurane group. There were no significant differences in serum concentrations of CK or AST between patients with and without fasciculations. In addition, we did not observe any significant correlation between age and CK concentrations during sevoflurane or isoflurane anaesthesia.

Mean basal serum CK concentrations in the sevoflurane group were 97.3 (SD 17.3) iu litre$^{-1}$ before anaesthesia, which increased to 478 (170) iu litre$^{-1}$ ($P<0.05$) 20 h after injection of suxamethonium. In the isoflurane group, basal serum CK concentrations were 86.9 (22.4) iu litre$^{-1}$ before anaesthesia and 628 (223) iu litre$^{-1}$ ($P<0.05$) 20 h after injection of suxamethonium. Basal AST concentrations in the sevoflurane group were 17.5 (4.9) iu litre$^{-1}$ before anaesthesia, which increased significantly to 31.7 (3.5) iu litre$^{-1}$ ($P<0.05$) 20 h after suxamethonium. In the isoflurane group, basal serum AST concentrations were 17.3 (2.4) iu litre$^{-1}$ before anaesthesia, increasing significantly to 34.8 (5.7) iu litre$^{-1}$ ($P<0.05$) 20 h after administration of suxamethonium. Mean serum CK and AST concentrations in the sevoflurane group were significantly lower ($P<0.05$) than those in the isoflurane group, 20 h after suxamethonium. Mean serum CK and AST concentrations 30 min after administration of suxamethonium were 113.4 (6.5) and 20.3 (1.7) iu litre$^{-1}$ in the sevoflurane group and 115.8 (7.0) and 22.1 (2.3) iu litre$^{-1}$ in the isoflurane group. There were no significant differences in serum ALT and LDH concentrations between groups, 30 min and 20 h after suxamethonium (table 2).

## Discussion

Suxamethonium is known to increase serum CK and myoglobin concentrations when given during halothane or enflurane anaesthesia and to produce larger increases in serum concentrations of these enzymes in paediatric patients.[5 6] It has been reported that plasma CK and myoglobin concentrations do not correlate with fasciculations after suxamethonium,[9] although children are known not to fasciculate. Increased CK concentrations in children after suxamethonium could be caused by muscle prematurity, making the muscle prone to release CK or to increase muscle content of CK.[5]

Tano and Fujiwara[10] reported that serum CK concentrations 20 min after administration of suxamethonium during sevoflurane anaesthesia were similar to those during halothane anaesthesia. Noguchi and colleagues[11] found that serum CK and myoglobin concentrations after suxamethonium were lower in patients receiving sevoflurane than in those receiving halothane 60 min after suxamethonium. However, in these studies CK concentrations were measured 20 and 60 min after suxamethonium, well before serum CK concentration reaches its peak, at 9–24 h after administration of suxamethonium.[6]

In our study, serum CK concentrations, measured 20 h after suxamethonium, were increased markedly in both groups, in contrast with findings of previous reports.[5 11 12] Moreover, we found that the peak serum concentration of CK was higher in the isoflurane than in the sevoflurane group. The increased serum CK originated from skeletal muscle where most of the enzyme is located. Acute muscle necrosis or sudden changes in the permeability of the sarcolemma may be responsible for the increase in serum CK concentrations.[13] Serum increases in AST concentrations were also caused by damage to skeletal muscle because postoperative ALT and LDH values were unchanged. Thus differences in serum CK and AST concentrations between both groups may be related to differences in the effects of both anaesthetics on skeletal muscle. The reasons for the higher CK concentrations during isoflurane anaesthesia are unclear. We hypothesize that the immaturity of skeletal muscle in children makes it either prone to release more CK or be richer in CK. In addition, differences in concentrations of CK and AST after suxamethonium between the two anaesthetics may result from differences in intracellular reactions triggered by anaesthetics or from differences in the permeability of the muscle cell membrane to anaesthetics. Using skinned fibres, isoflurane was more potent than sevoflurane, producing $Ca(^{2+})$-induced $Ca^{2+}$ release (CICR).[14] CICR, which plays an important role in the diagnosis of malignant hyperthermia (MH), may not be directly related to CK release. However, it is interesting that isoflurane, which was more potent than sevoflurane in the test for MH, was also associated with higher concentrations of CK after suxamethonium in our study.

Heart muscle, liver, skeletal muscle and kidney are rich in AST and ALT. LDH is present in high concentration in the kidney, heart muscle and skeletal muscle. AST, ALT and LDH increase in the presence of severe muscle damage. In this study, both CK and AST increased significantly while ALT and LDH did not. The increase in CK during surgery is caused mainly by skeletal muscle injury. However, in our study it was probably a result of an increase in muscle membrane permeability, because minor surgery such as tonsillectomy has little effect on skeletal muscle. Thus the mechanism leading to increased CK in our study is probably different from that after exercise. In our study, serum CK concentrations were increased markedly by suxamethonium 1 mg $kg^{-1}$ in combination with both anaesthetics. A higher amount of suxamethonium would probably lead to higher serum CK concentrations.

In summary, we have demonstrated that sevoflurane preserved skeletal muscle integrity more than isoflurane when suxamethonium was used during induction of anaesthesia. However, because of the marked increase in serum CK concentrations with both anaesthetics, anaesthetists should carefully weigh the risks and benefits of the use of suxamethonium in children during isoflurane or sevoflurane anaesthesia, in spite of the fact that no clinical signs were observed in this study.

# Hypnotic effect of i.v. propofol is enhanced by i.m. administration of either lignocaine or bupivacaine

I. BEN-SHLOMO, M. TVERSKOY, G. FLEYSHMAN AND G. CHERNIAVSKY

## Summary

We have compared the hypnotic requirements for i.v. propofol when combined with i.m. lignocaine or bupivacaine. Ninety women (ASA I, II) undergoing minor gynaecological surgery were allocated randomly to one of nine groups of 10 patients to receive propofol combined with i.m. lignocaine, bupivacaine or saline, respectively. Propofol was administered in bolus doses of 0.2 mg kg$^{-1}$ every 30 s until loss of response to verbal command was achieved. Lignocaine and bupivacaine significantly enhanced the hypnotic effect of propofol in a dose-dependent manner. The maximum doses tested (lignocaine 3.0 mg kg$^{-1}$ and bupivacaine 1.0 mg kg$^{-1}$) reduced the hypnotic dose of propofol by 34.4% and 39.6%, respectively. We conclude that if lignocaine or bupivacaine is injected into soft tissue before induction of anaesthesia by propofol, the i.v. dose of the latter should be modified accordingly. (*Br. J. Anaesth.* 1997; **78**: 375–377).

**Key words**
Anaesthetics i.v., propofol. Anaesthetics local, lignocaine. Anaesthetics local, bupivacaine. Interactions (drug).

There is a growing interest in possible interactions of local and regional anaesthesia with drugs used for general anaesthesia.[1–5] Recently, we have shown that bupivacaine-induced spinal block significantly reduced the hypnotic requirements for thiopentone, midazolam and propofol.[3 4] Interestingly, the magnitude of this effect was not uniform for all of these drugs, which suggests an effect additional to, and distinct from, spinal block. However, no systematic evaluation of the effect of lignocaine on the hypnotic requirements of propofol was carried out.

A possible drug interaction with local anaesthetics which may modify the effect of general anaesthetics is of clinical relevance. At times, a dose of local anaesthetic is injected to provide pain relief for a surgical procedure, but is either insufficient or ineffective. When this happens, the anaesthetist is faced with a patient who already received a dose of local anaesthetic drug into a soft tissue location, but still needs general anaesthesia.

In order to evaluate possible interactions between lignocaine and bupivacaine, we have carried out this prospective, double-blind study.

## Patients and methods

With informed consent and approval of the Institutional Review Board, we studied 90 women, aged 20–50 yr, ASA I or II, weighing 50–90 kg, undergoing minor elective gynaecological surgery. Patients did not receive premedication and were allocated randomly to one of nine subgroups, divided further into three groups: in group 1, 40 patients received one of four doses of i.m. 4% lignocaine (0.5, 1.0, 2.0 and 3.0 mg kg$^{-1}$, 10 patients for each dose), administered into the gluteus muscle 10 min before induction of anaesthesia; in group 2, 40 patients received one of four doses of i.m. 0.5% bupivacaine (0.25, 0.5, 0.75 and 1.0 mg kg$^{-1}$, 10 patients for each dose), administered into the gluteus muscle 30 min before induction of anaesthesia. Intervals between i.m. injection of lignocaine or bupivacaine and i.v. injection of propofol were planned in the light of pharmacokinetic considerations regarding injection of these local anaesthetics into skeletal muscle or fat tissue.[6] Administration of the hypnotic drug was scheduled therefore to achieve these intervals. In group 3, 10 patients served as controls who received i.m. saline 3 ml into the gluteus muscle 10 min before induction of anaesthesia. No patient complained of local pain at the injection site that lasted for more than a few seconds.

Inability to respond to a simple command was used as the end-point for hypnosis ("open your eyes!", said twice). Propofol was administered i.v. over 5 s in bolus doses of 0.2 mg kg$^{-1}$ every 30 s. Response to verbal commands was evaluated 25 s after each bolus. The total dose required to achieve loss of response in each patient was recorded in mg kg$^{-1}$.

One physician administered propofol and monitored the response to verbal command (G. C.). He was unaware of the dose or type of local anaesthetic (or saline) administered earlier. On completion of the experimental evaluation, anaesthesia was continued and complemented with additional agents, as indicated clinically.

Analysis of variance (ANOVA) was used to evaluate the difference between the subgroups of 10

patients, as reflected by *t* test. A simple regression analysis was used to evaluate the significance of trends. $P<0.05$ was regarded as the threshold for significance.

## Results

There were no differences in age or weight between the nine subgroups of 10 patients (table 1). The mean dose of propofol for hypnosis in group 3 (control) was 1.844 (SD 0.273) mg kg$^{-1}$. Progressive reduction of the hypnotic dose was noted for both lignocaine and bupivacaine (figs 1, 2, respectively). The lowest doses of lignocaine and bupivacaine tested (0.5 and 0.25 mg kg$^{-1}$, respectively) did not reduce significantly the hypnotic dose of propofol. The first dose of lignocaine which significantly reduced the hypnotic dose of propofol was 1.0 mg kg$^{-1}$, and that for bupivacaine 0.5 mg kg$^{-1}$. The highest doses of lignocaine and bupivacaine tested in this study (3.0 mg kg$^{-1}$ and 1.0 mg kg$^{-1}$, respectively) reduced the hypnotic requirements for propofol by 34.4% and 39.6%, respectively. The trends in reduction (on a log-dose scale) in propofol hypnotic requirements were $r^2$=0.476 and $r^2$=0.706 for lignocaine and bupivacaine, respectively ($P$=0.0001 in both cases). The respective slopes of the two curves were −0.612 (95% confidence interval −0.437 to −0.823) and −1.064 (−1.29 to −0.876), indicating a significantly steeper curve for bupivacaine.

*Table 1* Age (mean) and weight (mean (SD)) in the different groups of patients in the study on the interaction between propofol and local anaesthetics

| Group | Local anaesthetic (mg kg$^{-1}$) | | Age (y) | Weight (kg) |
|---|---|---|---|---|
| 1 | Lignocaine | 0.5 | 30.7 | 64.2 (8.3) |
| | | 1.0 | 38.8 | 59.4 (10.3) |
| | | 2.0 | 38.0 | 68.8 (12.4) |
| | | 3.0 | 35.1 | 66.5 (10.4) |
| 2 | Bupivacaine | 0.25 | 34.2 | 68.5 (8.7) |
| | | 0.50 | 33.5 | 63.6 (8.4) |
| | | 0.75 | 33.9 | 62.9 (6.8) |
| | | 1.00 | 34.9 | 65.6 (6.7) |

The values inside each bar are the actual doses (SD) in mg kg$^{-1}$. *$P<0.05$ compared with control or bupivacaine 0.25 mg kg$^{-1}$; †$P<0.05$ compared with control and all lower doses of bupivacaine.

## Discussion

The hypnotic dose of propofol for the control group in this study (mean 1.844 (SD 0.273) mg kg$^{-1}$) was within the recommended range for induction of anaesthesia (1.5–3.0 mg kg$^{-1}$).[7] The highest doses of local anaesthetics were less than half the recommended maximum clinical doses.[6] Local anaesthetics are known to have some influence on the central nervous system[8] which are not unlike some of the characteristics of general anaesthetics. The interaction between local anaesthetics and propofol was tested mainly for two aspects of their common use; namely, alleviation of local pain caused by propofol[9] and use of local lignocaine preparations to blunt cardiovascular responses to tracheal intubation.[10] It has been reported that mucosal absorption is less than that observed with direct injection.[11] Nevertheless, in the above studies possible modification of the hypnotic dose of propofol was not the central issue. In our study the interval between i.m. lignocaine or bupivacaine and i.v. administration of propofol was planned to be 10 and 30 min, respectively, because at these intervals blood concentrations of these agents reach a peak.[6] These intervals to peak blood concentrations are very close to those seen after extradural administration of both drugs.[12 13] Thus systemic interaction, superimposed on decreased afferent input, is most likely to be of the same nature.

The clinical relevance of our results lies in the growing use of local and regional alternatives for general anaesthesia, alternatives that do not invariably provide adequate pain relief. This in turn may lead to induction of general anaesthesia after previously injected local anaesthetics; in this situation physicians should be alert to the nature of the above interaction. Moreover, special attention should be devoted to bupivacaine as its interaction with propofol seemed to form a steeper curve. Whether the two local anaesthetics tested herein interact in the same way and magnitude with other general anaesthetics is currently under study.

# Occupational exposure to desflurane and isoflurane during cardiopulmonary bypass: is the gas outlet of the membrane oxygenator an operating theatre pollution hazard?

K. HOERAUF, M. HARTH, K. WILD AND J. HOBBHAHN

**Summary**

We have compared occupational exposure to isoflurane and desflurane during cardiopulmonary bypass, with and without a scavenging system at the membrane oxygenator outlet. Trace concentrations of volatile anaesthetics were measured by a direct reading instrument in 40 elective heart surgery procedures. Measurements were obtained in the breathing zones of the anaesthetist and perfusionist. When a scavenging system was used, median desflurane values were less than 0.3 ppm and isoflurane values less than 0.2 ppm. Without a scavenging system values were, in general, three- (isoflurane) to five- (desflurane) fold higher. We conclude that the use of a scavenging system at the membrane oxygenator outlet can reduce occupational exposure to volatile anaesthetics. We therefore recommend routine use of scavenging devices during cardiopulmonary bypass. (*Br. J. Anaesth.* 1997; 78: 378–380).

**Key words**
Anaesthetists, occupational exposure. Heart, cardiopulmonary bypass. Anaesthetics volatile, isoflurane. Anaesthetics volatile, desflurane. Operating rooms, contamination. Equipment, scavenging devices.

Exposure to traces of inhaled anaesthetic agents may impair the health of the operating theatre (OT) personnel. Although no cause–effect relationship has been found, most public health authorities recommend various occupational exposure standards to minimize possible health risks.[1] In the UK, a 50 ppm isoflurane occupational exposure standard as an 8-h time-weighted average has been published recently.[2] Occupational exposure standards for sevoflurane and desflurane have not yet been established.

Several efforts have been made to minimize exposure by improving the working environment. Effective air conditioning and scavenging of the anaesthesia machine outlets are used routinely to maintain waste gas concentrations low. Nevertheless, gas outlet ports on membrane oxygenators are not routinely connected to operating theatre exhaust systems, even though anaesthetic gases are being released at high flow rates (>5 litre $\text{min}^{-1}$) into the operating theatre.

The aim of this study was to determine exposure of the anaesthetist and perfusionist to desflurane and isoflurane during cardiopulmonary bypass, with and without the use of a scavenging system at the oxygenator outlet.

## Patients and methods

After approval by our institutional review board, we studied 40 patients (28 males), median age 64 (range 36–82) yr, undergoing elective coronary artery surgery. Patients were premedicated with clorazepate 20–30 mg orally on the evening before surgery, and clorazepate 20 mg approximately 1 h before operation. Anaesthesia was induced with fentanyl 5 $\mu g\ kg^{-1}$ i.v., followed by a sleep dose of etomidate. Neuromuscular block was produced with pancuronium 100 $\mu g\ kg^{-1}$. Anaesthesia was maintained before CPB with an infusion of propofol 5 mg $kg^{-1}\ h^{-1}$, supplemented with fentanyl bolus doses up to 20 $\mu g\ kg^{-1}$ and pancuronium 50 $\mu g\ kg^{-1}$. A standard CPB technique was used in all patients. Before aortic cannulation patients were anticoagulated with heparin 375 u. $kg^{-1}$. The bypass circuit consisted of a capillary membrane oxygenator (Maxima/plus, Medtronic, Anaheim, CA, USA) and a roller pump (Stöckert Instruments, Munich, Germany), which was primed with a crystalloid solution.

Patients were allocated randomly to one of four groups: group 1, isoflurane without scavenging system; group 2, desflurane without scavenging system; group 3, isoflurane with scavenging system; and group 4, desflurane with scavenging system. Treatment assignments were contained in sequentially ordered sealed envelopes, which were opened before induction of anaesthesia.

After application of the aortic cross clamp and administration of cold cardioplegic solution, time was allowed to develop a stable level of perfusion pressure and mild hypothermia (32–33 °C). Thereafter volatile anaesthetics were administered during CPB to provide anaesthesia and to control

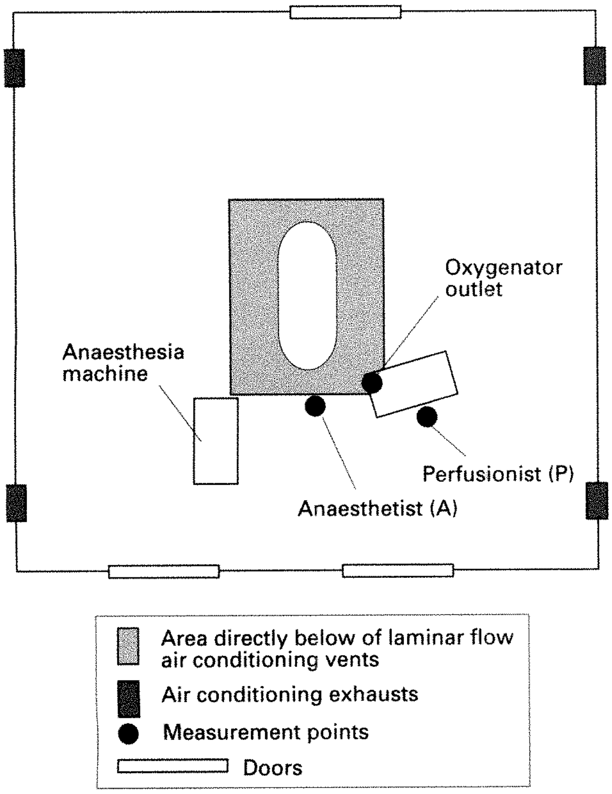

*Figure 1* Ground plan of the operating room with the locations of the measurement points.

arterial pressure, as described previously.[3] The volatile anaesthetics were administered via a vaporizer inserted into the oxygenator gas supply line with a constant gas flow of 3 litre $min^{-1}$. Concentrations were measured using a Datex Capnomac (Helsinki, Finland) at the oxygenator outlet.

### WORKPLACE DESCRIPTION

The oxygenator outlet was connected to the hospital's central scavenging system with a suction flow of 60 litre $min^{-1}$. To avoid negative pressure at the exhaust port of the oxygenator, a hole (0.5 $cm^2$) was placed proximal to the outlet of the oxygenator to provide a pressure balance and avoid malfunction.

The air volume of the operating theatre in this study was 130 $m^3$. Ventilation and air conditioning systems were separate from those serving other rooms of the hospital. Air conditioning was performed by a laminar flow system producing an air exchange rate of 2600 $m^3$ per hour (20 exchanges/hour) without recirculation. The location of the area below the air conditioning vents is shown in figure 1. The exhaust outlets of both the anaesthesia machine and the infrared analyser were connected to the central scavenging system of the hospital.

### DATA ACQUISITION AND ANALYSIS

Measurements of trace concentrations were obtained every 2 min in the breathing zones of the anaesthetist and perfusionist using a highly sensitive direct reading instrument (Bruel and Kjaer 1302, Naerum, Denmark) which is a photoacoustic infrared spectrometry device. The system was calibrated for each substance with trace gas mixtures, for example 15.3 ppm of isoflurane in pure nitrogen. The lower detection limit was 0.01 ppm for both anaesthetics and accuracy was within ±2% over a linear range of 0.01–1000 ppm.

Data acquisition was performed using an IBM compatible computer system (Intel 486 processor, 66 MHz, running under MS-DOS 6.22) and statistical analysis was performed by means of the SPSS for Windows 6.1 software.

Mean trace concentrations were calculated for each anaesthetic from the area under the curves derived from intermittent measurements. Mean concentrations of individual anaesthetics are presented as median (range) for each location and group. Statistical comparisons were made using the Wilcoxon test ($P<0.05$).

## Results

Desflurane was administered in concentrations of 2.6–5.2 vol% and isoflurane at 0.55–1.1 vol% during cardiopulmonary bypass only. Mean bypass times were 87.3 (SEM 11.2) min in group 1, 85.6 (12.5) min in group 2, 80.6 (9.4) min in group 3 and 78.4 (4.07) min in group 4.

Trace concentrations are presented in table 1. Without a scavenging system exposure to desflurane and isoflurane was 3–5 times higher than that with scavenging. Figure 2 shows a typical recording with and without a scavenging system during desflurane anaesthesia. The NIOSH occupational

*Table 1* Median (range) mean trace concentrations of the single measurements. Values are in parts per million (ppm). *$P<0.05$ between "scavenging" and "no scavenging"

| | Group 1 (isoflurane) (no scavenging) | Group 2 (desflurane) (no scavenging) |
|---|---|---|
| Anaesthetist | 0.31 (0.15–2.08) | 0.90 (0.56–6.08) |
| Perfusionist | 0.33 (0.15–2.10) | 0.93 (0.54–6.10) |
| | Group 3 (isoflurane) (scavenging) | Group 4 (desflurane) (scavenging) |
| Anaesthetist | 0.14 (0.13–0.19)* | 0.24 (0.09–0.81)* |
| Perfusionist | 0.16 (0.13–0.20)* | 0.26 (0.10–0.79)* |

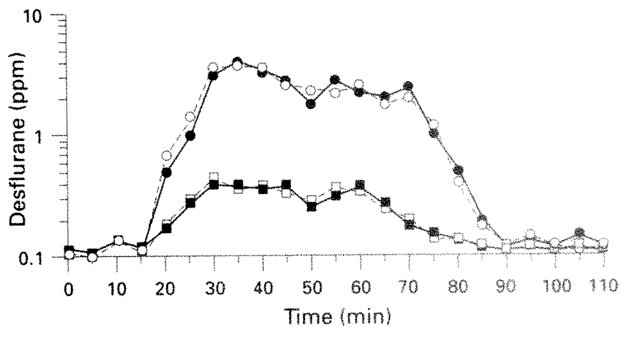

*Figure 2* Example of time-dependent waste gas concentrations of two anaesthetic procedures with identical CPB times. Exposure values for the anaesthetist (■, ●) and perfusionist (□, ○) are indicated as ■, □ (scavenged) and ●, ○ (non-scavenged), respectively.

exposure standard of 2 ppm was exceeded in several cases without using a scavenging system. With a scavenging system, all values were less than 1 ppm.

In general, exposure to desflurane was higher than that to isoflurane, with and without scavenging the membrane oxygenator outlet. However, the differences were not as high as expected from the differences in concentration in the oxygenator. There were no differences in exposure of the anaesthetist or perfusionist.

## Discussion

Volatile anaesthetics are often used during hypothermic cardiopulmonary bypass, because of their vasodilator and anaesthetic properties, to produce unconsciousness and suppression of reflex responses to noxious stimulation.[3] Whereas isoflurane is used routinely, desflurane (difluoromethyl 1-fluoro 2,2,2-trifluoro ethyl ether) has only recently become available for clinical use in the USA and Europe. Desflurane has also been used for cardiac surgery and it appears to have haemodynamic effects similar to those of isoflurane.[4] These substances contaminate operating theatre air, leading to chronic exposure to trace concentrations of inhaled anaesthetics, which may be hazardous to health.[5-8] These suggestions are based mainly on epidemiological studies. The limitations of these studies have been discussed elsewhere.[9-13] Because of flaws in the epidemiological investigations and lack of data on dose relationships, it has not been possible to establish an aetiological connection between untoward health responses and waste anaesthetic gases. However, the potential risk of harmful effects from chronic occupational exposure to gaseous anaesthetics has led to the setting up of occupational exposure standards.

In European countries, recommended occupational exposure standards are specific for individual agents and range from 20 ppm (Germany) to 50 ppm (UK) and are mostly related to an 8-h time-weighted average exposure.[1 2] In contrast, the US National Institute for Occupational Safety and Health (NIOSH) recommends a global occupational exposure standard of 2 ppm for all halogenated agents related to an average over the period of anaesthetic administration.[14] This occupational exposure standard is based mainly on the lowest level detectable using the sampling and analysis techniques recommended by NIOSH in 1977.[14]

As pollution of the operating theatre cannot be prevented in general, health authorities have developed technical procedures (e.g. sampling methods, leak test procedures, medical surveillance and training methods) to keep exposure to waste anaesthetic gases low.

It has been shown recently that under modern working conditions and with respect to these recommendations, occupational exposure to sevoflurane, isoflurane and enflurane can mostly be kept lower than 2 ppm.[15-17]

In this study, waste gas concentrations did not exceed 10 ppm, despite a high leakage of 5 litre $\text{min}^{-1}$ with 0.5–5 vol% (5000–50000 ppm) of volatile anaesthetics. Occupational exposure was low because of an effective air conditioning system with 20 air exchanges per hour. In spite of low concentrations in the working area, this study demonstrated that the use of a scavenging system reduced occupational exposure to volatile anaesthetics further. This may be relevant, particularly in an operating theatre with lower air exchange rates of the air conditioning system.

We therefore recommend routine use of scavenging devices during cardiopulmonary bypass to keep exposure to inhaled anaesthetics low.

# Effects of chronic β-blockade on compensatory mechanisms during acute isovolaemic haemodilution in patients with coronary artery disease

D. R. SPAHN, B. SEIFERT, T. PASCH AND E. R. SCHMID

## Summary

We have compared compensatory mechanisms during acute isovolaemic haemodilution of 12 ml/kg body weight of blood with hydroxyethyl starch (450 000/0.7) exchange, in non-β-blocked and β-blocked patients with coronary artery disease. During haemodilution, mean concentrations of haemoglobin decreased from 12.8 (SEM 0.2) to 10.1 (0.1) g $dl^{-1}$ ($P<0.01$). Only β-blocked patients had an increase in cardiac index ($P<0.01$); in non-β-blocked patients, cardiac index remained constant. In both groups oxygen extraction increased ($P<0.01$), but the increase tended to be greater in non-β-blocked patients ($P=0.06$). Oxygen consumption was maintained in both groups. There were no ECG signs of myocardial ischaemia. We conclude that β-blocked and non-β-blocked patients with coronary artery disease tolerated well moderate haemodilution to a haemoglobin value of approximately 10 g $dl^{-1}$, however, compensatory haemodynamic mechanisms differed fundamentally between the two groups. (*Br. J. Anaesth.* 1997; **78**: 381–385).

**Key words**
Blood, haemodilution. Surgery, cardiovascular. Heart, coronary artery bypass. Pharmacology, antagonists adrenergic.

Increases in cardiac output and oxygen extraction are the two major compensatory mechanisms during acute isovolaemic haemodilution.[1] The effect of chronic β-adrenergic blocker therapy on these compensatory mechanisms, however, is largely unknown in patients with coronary artery disease.[1]

Acute i.v. β-adrenergic block did not compromise an increase in cardiac output in animals undergoing experimental haemodilution,[2–4] but short-term oral β-adrenergic blocker therapy blunted this compensatory mechanism.[5 6] Conversely, long-term β-adrenergic blocker therapy resulted in an increase in myocardial β-adrenergic receptors[7 8] with a concomitant increase in left ventricular ejection fraction in patients with congestive heart failure.[7 9–11] Chronic β-adrenergic blocker therapy therefore could modify the increase in cardiac output during haemodilution.

We have compared prospectively haemodynamic compensatory mechanisms in patients receiving chronic β-adrenergic blocker therapy and those not receiving β-adrenergic blockers, undergoing coronary artery bypass surgery during preoperative isovolaemic haemodilution.

## Patients and methods

With approval of the local Ethics Committee and written informed consent, over a period of 2 yr we studied 20 consecutive patients not receiving β-adrenergic blocker therapy and 62 chronically β-blocked patients undergoing elective first-time coronary artery bypass graft (CABG) surgery. The chronically β-blocked patients were studied in a variety of different designs but were haemodiluted in the same way as the non-β-blocked patients (see below). These 62 chronically β-blocked patients served as a pool from which patients matched for age and left ventricular ejection fraction were selected for comparison. For each of 20 non-β-blocked patients, two β-blocked patients matched for age and left ventricular ejection fraction were chosen by a person with no other knowledge of patient characteristics. Thus the final groups comprised 20 non-β-blocked and 40 β-blocked patients. Ejection fraction was derived digitally from cineangiography.

Exclusion criteria for β-blocked and non-β-blocked patients were myocardial infarction within 10 days, unstable angina (heparin and nitroglycerin infusions and being cared for in the intensive care unit), concomitant valvular cardiomyopathy, left main coronary artery stenosis of more than 50%, absence of sinus rhythm, presence of left bundle branch block and a preoperative haemoglobin concentration of less than 11 g $dl^{-1}$. Patients were not excluded on the basis of a low ejection fraction or advanced age.

The evening before operation and also on the morning of operation, patients received their regular cardiovascular drugs, including β-blockers (when applicable), calcium entry blockers and nitrates.

Angiotensin converting enzyme (ACE) inhibitors were not given on the morning of operation corresponding to an institutional practice in patients undergoing CABG surgery. The preoperative β-blocking regimen consisted of atenolol in 27 patients (daily doses of 25 mg in two, 50 mg in 17 and 100 mg in eight patients), metoprolol in eight patients (daily doses of 50 mg in two, 100 mg in one and 200 mg in one patient), bisoprolol (5 mg) in two patients and propranolol (60 mg), bopindolol (1 mg) and celiprolol (200 mg) in one patient each. Patients were premedicated with oral flunitrazepam 1–2 mg, approximately 2 h before induction of anaesthesia.

In the anaesthesia induction area, patients were monitored with pulse oximetry and five-lead ECG, and a peripheral venous cannula and a radial arterial cannula were inserted. Patients were given Ringer's lactate 5 ml $kg^{-1}$. Anaesthesia was induced with fentanyl and midazolam, and neuromuscular block was produced with pancuronium. Anaesthesia was maintained with infusions of fentanyl 0.05 $\mu g\ kg^{-1}\ min^{-1}$ and midazolam 0.75 $\mu g\ kg^{-1}\ min^{-1}$.[12] After tracheal intubation a triple-lumen central venous catheter and a pulmonary artery catheter were inserted via the right internal jugular vein. An additional large gauge (14-gauge) catheter was inserted into a cubital vein of the contralateral arm for future removal of blood. The lungs were ventilated mechanically to normocapnia using an air–oxygen mixture with an inspiratory oxygen concentration of 50% and a ventilatory frequency of 10 bpm.

After baseline measurements, patients were haemodiluted in a two-step procedure. Initially, 6 ml/kg body weight (BW) of blood was removed from the cubital vein and replaced simultaneously and isovolaemically with 6% hydroxyethyl starch over 15–20 min (450 000/0.7) (Plasmasteril, Fresenius AG, Bad Homburg, Germany) according to central venous pressure, that is maintaining central venous pressure stable at each patient's individual level before haemodilution. Thirty minutes after the first measurement, a second set of measurements was performed. An additional 6 ml/kg BWof blood was then exchanged with 6% hydroxyethyl starch (total 12 ml/kg BW) over 15–20 min and a third set of measurements was performed 60 min after the first measurement. During haemodilution no other drugs (apart from fentanyl and midazolam infusions) and no other infusions (apart from 6% hydroxyethyl starch (450 000/0.7)) were administered. All measurements were performed before surgery. Measured variables were: heart rate, systemic and pulmonary artery pressures, central venous pressure, pulmonary capillary wedge pressure, cardiac output measured by thermodilution (10 ml of cold saline injections), arterial and mixed venous blood-gas tensions (BGElectrolytes and IL482 Co-Oximeter, Instrumentation Laboratory, Inc., Lexington, MA, USA), ST segments (J+60 ms[13]) in leads II and V5[14] and rectal temperature. From these variables, cardiac index, systemic and pulmonary vascular resistances, and oxygen delivery, oxygen consumption, oxygen extraction and arteriovenous oxygen difference were computed according to standard formulae.[15]

Changes during haemodilution were compared using repeated measures analysis of variance with Greenhouse–Geisser correction (Superanova 1.11, Abacus Concepts, Inc., Berkeley, CA, USA) followed by paired *t* tests with Bonferroni correction (Statview 4.02, Abacus Concepts, Inc., Berkeley, CA, USA). Patient characteristics and baseline data were compared using unpaired *t* tests and Fisher's exact tests. $P<0.05$ was considered statistically significant. Data are presented as mean (SEM).

## Results

### PREOPERATIVE PATIENT CHARACTERISTICS

Non-β-blocked and β-blocked patients were similar in preoperative characteristics (table 1); the only difference was a lower heart rate in β-blocked patients on the evening before operation. Similar amounts of fentanyl, midazolam and pancuronium were used for induction of anaesthesia in the non-β-blocked and β-blocked patients.

### BASELINE DATA

At baseline, during anaesthesia and immediately before haemodilution, the two groups were very similar (table 2, fig. 1); only PCWP was slightly higher in non-β-blocked patients and the ST segment in lead II was marginally negative in non-β-blocked patients, whereas it was minimally positive in β-blocked patients.

### RESPONSE TO HAEMODILUTION

During haemodilution, haemoglobin concentrations decreased from 12.7 (0.3) to 10.0 (0.3) g $dl^{-1}$ in non-β-blocked patients and from 12.8 (0.2) to 10.1 (0.1) g $dl^{-1}$ in β-blocked patients (table 2). Filling pressures were constant in both groups (table 2). Cardiac index, however, increased only in β-blocked patients whereas in non-β-blocked patients cardiac index remained unchanged during haemodilution (fig. 1A). Oxygen extraction increased in both groups during haemodilution but the increase tended to be greater in non-β-blocked patients ($P=0.06$) (fig. 1B). Correspondingly, a slightly more exaggerated decrease in mixed venous oxygen saturation in non-β-blocked patients ($P=0.05$) was observed (table 2). However, this was not substantiated in (Bonferroni corrected) *post hoc t* tests ($0.025<P<0.05$) (table 2). Oxygen delivery decreased similarly in non-β-blocked and β-blocked patients during haemodilution (table 2). Oxygen consumption was unchanged in non-β-blocked patients and increased minimally in β-blocked patients (table 2). ST segments in lead II were unchanged during haemodilution in both groups. ST segments in lead V5 were unchanged during haemodilution in non-β-blocked patients and became minimally less negative in β-blocked patients (table 2); this was not statistically significant in *post hoc t* tests with Bonferroni correction ($0.025<P<0.05$) (table 2).

Heart rate was generally higher in non-β-blocked patients but decreased in both groups during

unchanged during haemodilution in non-β-blocked patients but increased slightly in β-blocked patients (table 2). Pulmonary vascular resistance was unchanged during haemodilution in both groups (table 2).

$Pa_{O_2}$ increased similarly during haemodilution and $Pa_{CO_2}$ decreased slightly in both groups (table 2). Base excess and bicarbonate decreased during haemodilution similarly in both groups. pH was stable during haemodilution in both groups. Arteriovenous oxygen difference was unchanged in non-β-blocked patients but decreased in β-blocked patients during haemodilution (table 2).

## Discussion

We have found that chronically β-blocked and non-β-blocked patients with coronary artery disease tolerated well moderate isovolaemic haemodilution to a haemoglobin concentration of approximately 10 g dl$^{-1}$. However, compensatory haemodynamic responses of chronically β-blocked and non-β-blocked patients differed. While chronically β-blocked patients compensated for acutely lower arterial oxygen content by increases in cardiac index and oxygen extraction, non-β-blocked patients demonstrated an increase in oxygen extraction only and there was no increase in cardiac index.

As short-term oral β-adrenergic blocker therapy reduced the increase in cardiac index in animals undergoing experimental haemodilution,[5 6] a blunted increase in cardiac index might also be expected in chronically β-blocked patients during preoperative haemodilution. However, we observed the opposite, namely an increase in cardiac index exclusively in chronically β-blocked patients whereas cardiac index did not increase during haemodilution in non-β-blocked patients (fig. 1A). This might be because of increased numbers of myocardial β-adrenergic receptors, as observed during long-term β-adrenergic blocker therapy,[7 8] resulting in increased exercise capacity[10] and an exaggerated response to exogenous catecholamines such as dobutamine.[8] As endogenous catecholamines increase during acute isovolaemic haemodilution[16 17] and this is considered an important mechanism for the increase in cardiac index,[1] it is conceivable that after long-term oral β-blocker therapy patients may respond with a greater increase in cardiac index compared with non-β-blocked patients.

Alternative explanations for why non-β-blocked patients responded differently to haemodilution have to be considered. Oral β-blockade is initiated frequently in the medical treatment of coronary artery disease in the referral area of our hospital. Thus non-β-blocked patients might represent a particular selection of patients. In 10 of the 20 non-β-blocked patients studied (50%) a specific reason existed why the referring physician chose not to prescribe oral β-blocker therapy. These reasons were chronic obstructive pulmonary disease (six patients), peripheral arterial occlusive disease (two patients), side effects of β-blocker therapy (one patient) and symptomatic bradycardia before initiation of β-blocker therapy (one patient). In the remaining 10 patients no specific reason was found in the medical history why oral β-blocker therapy had not been given. Left ventricular ejection fraction was *not* lower in these patients without a clear reason for not being β-blocked (57.6 (6.3) %) compared with patients with a reason (52.8 (7.5) %). Conversely, most patient characteristics and baseline data were similar in non-β-blocked and β-blocked patients. The only differences were a lower heart rate on the evening before CABG surgery in β-blocked patients (table 1), a slightly higher PCWP at baseline, that is immediately before haemodilution (table 2) and a slightly negative ST segment in ECG lead II at baseline (table 2). The lower heart rate and the lower PCWP are caused by long-term β-blocker therapy.[8 9 18] The effect of a slightly negative ST segment in ECG lead II at baseline in non-β-blocked patients compared with a slightly positive ST segment in this lead in β-blocked patients (table 2) on the differential response during haemodilution is difficult to judge. However, because the slightly negative ST segment in ECG lead II in non-β-blocked patients became minimally but significantly *less* negative during haemodilution, myocardial ischaemia induced by haemodilution in non-β-blocked patients is not a likely reason to explain the lack of increase in cardiac index during haemodilution. Also, the trend towards a higher incidence of myocardial infarction within 6 months before operation in the β-blocked patients (table 1) is not a likely reason for why these patients had an increase in cardiac output during haemodilution compared with non-β-blocked patients with a slightly lower incidence of recent myocardial infarction. Thus we consider such alternative explanations for the different response of non-β-blocked and β-blocked patients as relatively unlikely.

We did not observe ECG alterations suggestive of myocardial ischaemia in any patient (new ST depression >0.1 mV or a new ST elevation >0.2 mV[13]). However, the combined sensitivity of leads II and V5 to detect intraoperative myocardial ischaemia is only approximately 80%.[14] Thus there is a possibility that undetected myocardial ischaemia might have developed during haemodilution. This is unlikely because of the absence of secondary manifestations of ischaemia, such as cardiac arrhythmias, increases in PCWP or decreases in arterial pressure or cardiac index.[19]

# Perioperative myocardial cell injury: the role of troponins

H. METZLER, M. GRIES, P. REHAK, TH. LANG, S. FRUHWALD AND W. TOLLER

## Summary

Early recognition of minor myocardial cell injury and appropriate treatment may prevent development of myocardial infarction as one of the most severe postoperative cardiac complications. Troponins have been shown to be sensitive biochemical markers for the assessment of myocardial cell injury. We investigated prospectively 67 cardiac risk patients undergoing elective non-cardiac surgery. Troponin T (TNT) concentrations were measured during the perioperative period, and in those patients with increased TNT (cut-off 0.2 ng ml$^{-1}$), troponin I (TNI) concentrations were measured additionally (cut-off 0.6 ng ml$^{-1}$). Patients were allocated to one of three groups: group I, all patients with normal TNT concentrations had a good cardiac outcome (80.5%). In those patients with increased TNT concentrations (19.5%) TNI was also positive; group II, patients (8.8%) with only slightly increased TNT concentrations (0.32–0.99 ng ml$^{-1}$) also had a good outcome, indicating minor myocardial cell injury, whereas patients with cardiac complications (11.9%) had higher TNT concentrations (0.47–9.8 ng ml$^{-1}$) ($P<0.05$) (group III). With a TNT cut-off at 0.2 ng ml$^{-1}$, the positive predictive value for adverse outcome was 61.5%; the negative predictive value was 100%. With a TNT cut-off at 0.6 ng ml$^{-1}$, the positive predictive value for adverse outcome increased to 87.5%, but the negative predictive value was still high (98%). Most of the patients showed an increase in TNT content from the day of surgery until the third postoperative day. We conclude that serial troponin measurements during the perioperative period identify pre-, intra- and postoperative myocardial cell injury. The concentration of troponin T may reflect the degree of injury and help categorize the subsequent risk. (*Br. J. Anaesth.* 1997; **78**: 386–390).

**Key words**
Surgery, non-cardiac. Surgery, perioperative period. Complications, morbidity. Heart, troponins.

Recently, in cardiac risk patients undergoing non-cardiac surgery, a complete perioperative pattern of myocardial ischaemia has been identified.[1–7] Postoperative ischaemia appears to correlate with adverse outcome, and prolonged subendocardial ischaemia rather than acute coronary artery occlusion precedes cardiac complications.[1 2] Perioperative myocardial infarction (MI) represents the most severe complication at the end of an adverse cascade, usually initiated by episodes of myocardial ischaemia which may occur as a reversible or irreversible event. The gap between reversible myocardial ischaemia and definite death of myocardial cells of a major area may be linked by appropriate assessment of minor myocardial cell injury, which may help to prevent MI.

Cardiac troponins have been established as sensitive markers for detection of major and minor myocardial cell injury, avoiding the high incidence of false positive results associated with the use of CK-MB.[8–13] Both troponin T (TNT) and troponin I (TNI) are currently used. TNT has the advantage of a broad diagnostic window of up to 14 days and has been shown to be a marker for minor myocardial cell damage. TNI is expressed exclusively in the myocardium of adults and is highly specific for myocardial cell injury, excluding skeletal muscle damage. To date there have been no studies evaluating myocardial cell injury in the perioperative period using both troponins.

This study was designed to assess the extent of minor myocardial cell injury in cardiac risk patients undergoing elective non-cardiac surgery. The aims of the study were to examine the perioperative pattern of changes in troponin from the day before surgery until the fifth day after operation, to compare TNT and TNI concentrations in those patients with increased TNT concentrations and to compare the positive and negative predictive values of troponin T for adverse outcome.

## Patients and methods

After obtaining approval from the Ethics Committee of the University and informed consent, we investigated prospectively 70 cardiac risk patients undergoing elective non-cardiac surgery. Subjects were included in the study according to the presence of definite or at-risk coronary artery disease (CAD). Definite CAD was defined as previous MI, typical or atypical angina with positive exercise testing or scintigraphic evidence, or previous CABG or PTCA.

Accepted for publication: November 28, 1996.

Correspondence to H. M.

Patients at-risk for CAD were included if they had at least three of the following cardiac risk factors: age >65 yr, hypertension, current smoker, treated diabetes mellitus (insulin or oral hypoglycaemic agents), increased serum cholesterol concentration (>5.7 mmol $litre^{-1}$) or previous vascular surgery.

Before operation, patients were clinically evaluated; this included 12-lead ECG, chest x-ray and echocardiography. Premedication, anaesthesia and postoperative care were performed by clinicians not involved in the study and blinded to all research information. Twelve-lead ECG recordings were performed daily in the morning together with blood sampling (TNT, TNI, CK-MB) from the day before surgery until the fifth postoperative day.

### TROPONIN T ASSAY

Serum TNT was measured using an enzyme-linked immunosorbent assay with the Enzyme-Test-System ES 300 analyser (Boehringer Mannheim, Mannheim, Germany). The method is based on a single step sandwich principle with streptavidin-coated tubes as the solid phase and two monoclonal anti-human cardiac TNT antibodies. Values greater than or equal to 0.2 ng $ml^{-1}$ were considered positive.[13 14]

### TROPONIN I ASSAY

Serum cardiac TNI concentrations were measured using the Stratus Cardiac Troponin-I assay (Dade International Inc. Miami, FL, USA). This is a two-site immunoassay which uses two monoclonal antibodies that are specific for the cardiac isotype of TNI. Values greater than or equal to 0.6 ng $ml^{-1}$ were considered positive.[15]

### CK-MB ASSAY

Photometric determination of the activity of creatine kinase MB-isoenzyme (CK-MB) (*N*-acetylcysteine-activated) on an immunological basis (Granu Test 25, Merck, Darmstadt, Germany) was used. The reference range was ≤12 iu $litre^{-1}$ at 25 °C.

### ADVERSE CARDIAC OUTCOME

An adverse cardiac outcome was defined as the occurrence of unstable angina, severe cardiac arrhythmias compromising cardiovascular status, decompensated congestive heart failure (CHF), MI or cardiac death. MI was diagnosed using the following criteria: CK-MB >12 iu $litre^{-1}$ and electrocardiographic changes, that is development of either new Q-waves or persistent ST-elevation in the 12-lead ECG.

### STATISTICAL ANALYSIS

For comparison of patient groups with good and adverse outcomes the non-parametric Mann–Whitney test was used. $P<0.05$ was considered statistically significant. Changes in the TNI:TNT ratio were analysed by Friedman non-parametric two-way ANOVA.

## Results

Clinical data are summarized in table 1. Three patients were excluded because of incomplete samples for TNT or TNI analysis; 67 patients had complete 7-day profiles, with 469 single TNT samples and 91 TNI samples.

Of these 67 patients, 54 (80.5%) had normal and 13 (19.5%) had increased TNT concentrations, at least at one measurement. The times at which TNT were increased most frequently were on days 2, 3 and 4 after operation. No patient had increased TNT concentrations 24 h before operation, but two patients had increased concentrations on the morning of surgery.

Nine patients were still TNT positive at the end of the study (fig. 1). Most frequently, the first increase in TNT concentrations above the cut-off value were noted on the first and second postoperative days; two patients however, had a relatively late increase in TNT concentrations on day 4 after operation (fig. 2). Of the two patients with increased TNT concentrations

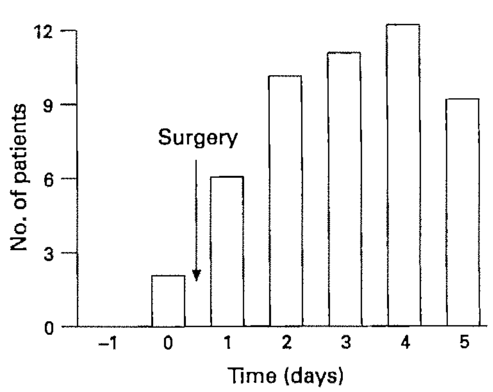

*Figure 1* Number of patients with increased TNT concentrations at different measurement times.

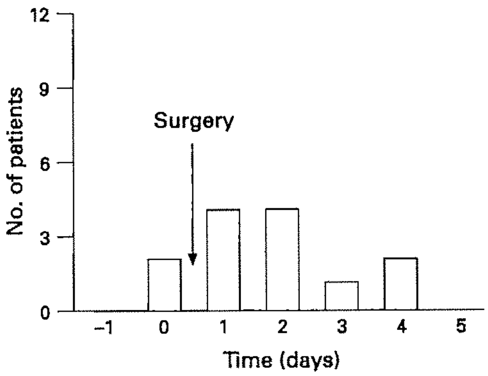

*Figure 2* Time when TNT concentrations first increased above the cut-off values.

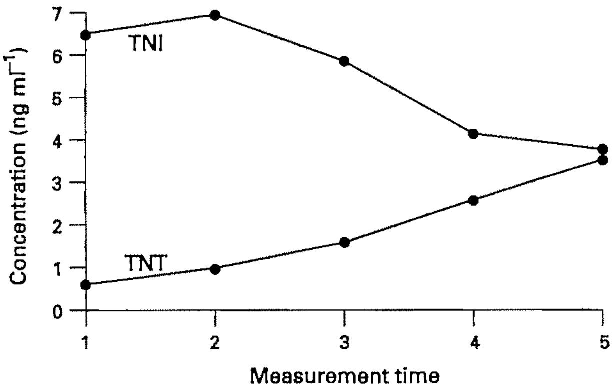

*Figure 3* Mean TNT and TNI concentrations for all patients with increased concentrations of TNT. Measurement times are numbered from the first above the cut-off value.

before operation, one developed CHF after operation. Of the six patients with an increase in TNT on the morning after surgery, four had intraoperative problems such as tachycardia, hypotension or hypertension. Two developed CHF immediately after surgery.

In all 13 patients with increased TNT concentrations, TNI concentrations were also above the cut-off value, although the pattern was different (fig. 3). Individual ratios for TNI:TNT decreased significantly from a mean value of 8.8 to 1.1 ($P<0.01$).

All patients with normal TNT concentrations had a good outcome (80.5%), except for one patient who died because of sudden severe bleeding from the femoral artery on day 10 after operation. In five patients (7.5%) TNT was positive, although there were no cardiac complications. All except one patient, however, had relatively low TNT values (<0.06, 0.32–0.99 ng ml$^{-1}$). Eight of the 13 patients (11.9%) with increased TNT concentrations (0.47–9.8 ng ml$^{-1}$) had an adverse outcome: three patients suffered from unstable angina, in three patients congestive heart failure occurred, one patient developed malignant arrhythmias and another postoperative non-Q-wave infarction. All eight patients had relatively high TNT values (fig. 4). The difference between groups 2 and 3 was significant ($P<0.05$). With a cut- off value for TNT of 0.2 ng ml$^{-1}$, the positive predictive value for adverse outcome was 61% and the negative predictive value was 100%. With a change in the cut-off to 0.6 ng ml$^{-1}$, the positive predictive value improved to 87%, but the negative predictive value was still high (98%).

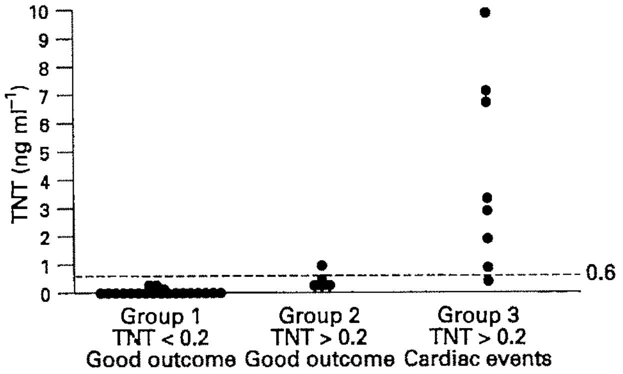

*Figure 4* TNT concentrations in relation to outcome.

A total of 76.9% of the patients with positive TNT values underwent vascular surgical procedures, although this subgroup represented only 56.7% of the total patient population. In contrast, the orthopaedic subgroup, representing 14%, demonstrated no increases in TNT.

There were no significant differences in patient characteristics between those with and without adverse outcomes or with and without increased TNT concentrations.

CK-MB was positive in 14 patients. Three patients had increased CK-MB concentrations, although both TNT and TNI were negative, and four patients had normal CK-MB concentrations, although both troponins were positive. By defining myocardial cell injury as an event with an increase in troponin T and I, the sensitivity of CK-MB was 70% and specificity was 94%. With the exception of one patient with preoperative renal insufficiency (creatinine 4.4 mg/100 ml) and constant high CK-MB concentrations of approximately 500 iu litre$^{-1}$, CK-MB concentrations were increased only for a short time, most often only 24 h.

Seven patients with increased TNT concentrations had transient ST-segment depression on the daily 12-lead ECG and one patient with MI showed ST-segment elevation. Three patients with an increase in troponin T concentrations did not show an increase in CK-MB or electrocardiographic changes.

## Discussion

The primary goal of postoperative biochemical monitoring of cardiac risk patients is to establish appropriate markers in order to detect early minor myocardial cell injury, to inhibit postoperative MI as one of the most threatening cardiac events and to exclude the existence of cardiac complications. Landesberg, Luria and Cotev demonstrated in major vascular surgery patients that cumulative prolonged subendocardial ischaemic events rather than shorter ischaemic periods are followed by cardiac complications.[2] Postoperative electrocardiographic ST-segment changes, however, indicate myocardial ischaemia which may or may not be followed by definite cell injury and require continuous ECG Holter monitoring.

Troponins have been introduced as sensitive biochemical markers of myocardial cell injury, both in medical patients and also in the postoperative period.[9 12 16] Katus, Schoeppenthau and Tanzeem were the first to study TNT concentrations after cardiac and non-cardiac surgery.[16] Adams, Sigard and Allen used TNI as a sensitive and specific method for the diagnosis of perioperative MI.[9] In the study of Lee, Thomas and Ludwig, increases in TNT were associated not only with MI but also with other major cardiac complications in patients without definite MI.[12] The results of our study allowed discrimination between three perioperative risk groups based on concentrations of troponin. No patient with TNT within the normal range had cardiac complications (group 1) and seven of eight patients with significantly increased values (group 3) suffered cardiac events. Between these two groups we found patients with only slightly increased TNT concentrations but without cardiac events, possibly resulting from minor, reversible myocardial cell injury. The cut-off in this series could be drawn at a concentration of 0.6 ng $ml^{-1}$ with only one false positive (group 2) and one false negative (group 3) result in each group. For our study population the higher cut-off value of 0.6 ng $ml^{-1}$ for troponin T appeared to better predict adverse outcome compared with 0.2 ng $ml^{-1}$.

The prolonged duration of our study (over 7 days), including the 24 h before surgery, allowed complete analysis of the beginning of cell damage. Although most of the injury occurred in the period from the day of surgery until the third postoperative day, two patients had a "late injury" profile, with normal TNT concentrations until day 3 after operation day and then an increase on day 4.

Two troponins are currently recommended for the diagnosis of myocardial cell injury. Increases in TNI concentrations are highly specific.[17 18] In contrast with TNT, TNI is not expressed in skeletal muscle throughout ontogeny.[17 18] TNT is a slightly larger protein than TNI and it has been used to stratify patients into high and low risk categories based on detection of minor myocardial cell damage.[14] Studies have demonstrated that in contrast with TNT or CK-MB, increases in TNI do not occur in acute or chronic muscle disease.[18 19] Cross- reactivity between cardiac and skeletal TNT appears to be 1–3% and may be decreased when specific monoclonal antibodies are used.

Therefore, we measured both troponins in those patients with increased TNT concentrations. Identical trends in TNT and TNI should exclude the probability of increases in TNT of non-cardiac origin. In this study, all patients with increased TNT concentrations also had positive TNI values. TNI reached the highest mean values at the first two measurement times and decreased afterwards, whereas mean TNT values increased gradually with the highest values at the fifth measurement time. We cannot account for this difference as there have been no studies comparing TNT and TNI trends in minor myocardial cell injury. The TNT and TNI content of the free cytoplasmic pool may differ. TNT has a higher molecular weight than TNI (33 000 *vs* 23 500 Da). Therefore, different release or clearance kinetic profiles, or both, may be responsible for this difference.

In addition to skeletal muscle injury, increases in TNT without a concomitant increase in TNI may be caused by renal disease.[20 21] In a recent study, Bhayana, Gougoulias and Cohoe demonstrated differences between results for TNT and TNI in renal patients.[20] They hypothesized three possible mechanisms: cross-reactivity of the assay, skeletal muscle gene expression of cardiac TNT or minimal cardiac damage. One patient in our study with preoperative renal insufficiency and constant increases in CK-MB showed a transient increase, but of both troponins.

The disadvantage of CK-MB as a biochemical marker of perioperative myocardial cell injury compared with troponins is not only its lower sensitivity and specificity but also the short diagnostic window of approximately 24 h.

# A study of the anatomy of the caudal space using magnetic resonance imaging

I. M. CRIGHTON, B. P. BARRY AND G. J. HOBBS

## Summary

We have studied, in 37 adult patients, the anatomy of the sacral extradural (caudal) space using magnetic resonance imaging The sacrococcygeal membrane (SCM) could not be detected in 10.8% of patients. The maximum depth of the caudal space adjacent to the SCM was beneath the upper third of the SCM in more than 90% of patients (mean depth 4.6 mm; range 1.0–8.0 mm). The shortest linear distance from the dura to the upper limit of the SCM varied considerably (60.5 mm; 34–80 mm) as did the volume of the caudal space excluding the foraminae and dural sac (14.4 $cm^3$; 9.5–26.6 $cm^3$). The dimensions of the caudal space and their variability have implications for clinical practice and a knowledge of these dimensions may increase both the reliability and safety of caudal techniques in adult patients. (*Br. J. Anaesth.* 1997; **78**: 391–395).

**Key words**
Anatomy, extradural space. Anaesthetic techniques, extradural. Measurement techniques, magnetic resonance imaging.

The caudal approach to the extradural space (caudal block) is used for intraoperative and postoperative analgesia for a variety of operations and for the management of chronic pain. The sacral hiatus marks the termination of the sacral canal and results from failure of fusion of the laminae of the fifth sacral vertebra. To perform a caudal block, the sacral hiatus must first be located and a needle passed through the sacrococcygeal membrane (SCM). This can be difficult or impossible at times because of wide anatomical variation in this region. A detailed understanding of the anatomy of the caudal region of the extradural space is therefore desirable for clinicians using this technique.

Current anatomical knowledge of this region is based largely on post-mortem studies from more than 50 yr ago. These were performed after a revival of interest in continuous caudal analgesia in obstetric practice.[1] In the same decade, the "recent" and skeletonized sacral anatomy of cadavers was studied[2] and the significance of variations in sacral anatomy for the use of caudal analgesia was discussed.[3] However, cadaveric dissection is subject to distortion and measurements may alter after skeletonization of the cadaver.[2] Furthermore, there have been anatomical changes in populations over the past 50 yr.

Recently, other anatomical areas such as the lumbar extradural region have been studied in life using magnetic resonance (MR) imaging.[4] The purpose of our study was to examine the normal anatomy of the sacral extradural (caudal) space in adults using MR imaging.

## Patients and methods

The study was carried out in the MR imaging suite at University Hospital, Nottingham. After a pilot study of 15 patients for familiarization and confirmation of the reproducibility of measurements, the anatomy of the caudal space relevant to the performance of caudal block was studied prospectively using MR images of 37 adult patients presenting for primary investigation of back pain. MR imaging was part of their routine investigation and no patient had evidence of congenital abnormalities such as spina bifida or a history of spinal surgery.

Patient height, weight and sex were recorded. MR imaging was performed with a Siemens Vision scanner operating at 1.5 T (tesla) with the patient supine. A phased array spine coil was used. The relevant anatomy was demonstrated most clearly using T2 sagittal plane images and consecutive T2 sagittal images of 0.44 cm thickness of the sacrum from the upper margin of S1 to the caudad limit of the sacral hiatus were therefore used (fig. 1). Using the Siemens computer software, measurements were made by two of the authors (I. M. C. and B. P. B.) using stored images for each patient on two separate occasions. If there was a discrepancy between measurements, a third measurement was made and the mean value recorded.

The length (fig. 2) and thickness (fig. 3) of the SCM (if present) were measured on the images giving the largest measurement. Only that part of the SCM through which the sacral canal could be entered with a needle, that is the length of the SCM with clearly visible underlying caudal space, was
